    12.1.3. Improving Quality of Care for Resource-Constrained Populations .................. 152
Preamble
Since 1980, the American College of Cardiology (ACC) and American Heart Association (AHA) have translated scientific evidence into clinical practice guidelines (guidelines) with recommendations to improve cardiovascular health. In 2013, the National Heart, Lung, and Blood Institute (NHLBI) Advisory Council recommended that the NHLBI focus specifically on reviewing the highest-quality evidence and partner with other organizations to develop recommendations (1, 2). Accordingly, the ACC and AHA collaborated with the NHLBI and stakeholder and professional organizations to complete and publish 4 guidelines (on assessment of cardiovascular risk, lifestyle modifications to reduce cardiovascular risk, management of blood cholesterol in adults, and management of overweight and obesity in adults) to make them available to the widest possible constituency. In 2014, the ACC and AHA, in partnership with several other professional societies, initiated a guideline on the prevention, detection, evaluation, and management of high blood pressure (BP) in adults. Under the management of the ACC/AHA Task Force, a Prevention Subcommittee was appointed to help guide development of the suite of guidelines on prevention of cardiovascular disease (CVD). These guidelines, which are based on systematic methods to evaluate and classify evidence, provide a cornerstone for quality cardiovascular care. The ACC and AHA sponsor the development and publication of guidelines without commercial support, and members of each organization volunteer their time to the writing and review efforts. Guidelines are official policy of the ACC and AHA.

Intended Use
Practice guidelines provide recommendations applicable to patients with or at risk of developing CVD. The focus is on medical practice in the United States, but guidelines developed in collaboration with other organizations can have a global impact. Although guidelines may be used to inform regulatory or payer decisions, they are intended to improve patients’ quality of care and align with patients’ interests. Guidelines are intended to define practices meeting the needs of patients in most, but not all, circumstances and should not replace clinical judgment.

Clinical Implementation
Management in accordance with guideline recommendations is effective only when followed by both practitioners and patients. Adherence to recommendations can be enhanced by shared decision making between clinicians and patients, with patient engagement in selecting interventions on the basis of individual values, preferences, and associated conditions and comorbidities.

Methodology and Modernization
The ACC/AHA Task Force on Clinical Practice Guidelines (Task Force) continuously reviews, updates, and modifies guideline methodology on the basis of published standards from organizations, including the Institute of Medicine (3, 4), and on the basis of internal reevaluation. Similarly, the presentation and delivery of guidelines are reevaluated and modified on the basis of evolving technologies and other factors to facilitate optimal dissemination of information to healthcare professionals at the point of care.

Toward this goal, this guideline continues the introduction of an evolved format of presenting guideline recommendations and associated text called the “modular knowledge chunk format.” Each modular “chunk” includes a table of related recommendations, a brief synopsis, recommendation-specific supportive text, and when appropriate, flow diagrams or additional tables. References are provided within the modular chunk itself to facilitate quick review. Additionally, this format will facilitate seamless updating of guidelines with focused updates as new evidence is published, as well as content tagging for rapid electronic retrieval of related recommendations on a topic of interest. This evolved approach format was instituted when this guideline was near completion; therefore, the present document represents a
transitional format that best suits the text as written. Future guidelines will fully implement this format, including provisions for limiting the amount of text in a guideline.

Recognizing the importance of cost–value considerations in certain guidelines, when appropriate and feasible, an analysis of the value of a drug, device, or intervention may be performed in accordance with the ACC/AHA methodology (5).

To ensure that guideline recommendations remain current, new data are reviewed on an ongoing basis, with full guideline revisions commissioned in approximately 6-year cycles. Publication of new, potentially practice-changing study results that are relevant to an existing or new drug, device, or management strategy will prompt evaluation by the Task Force, in consultation with the relevant guideline writing committee, to determine whether a focused update should be commissioned. For additional information and policies regarding guideline development, we encourage readers to consult the ACC/AHA guideline methodology manual (6) and other methodology articles (7-10).

Selection of Writing Committee Members
The Task Force strives to avoid bias by selecting experts from a broad array of backgrounds. Writing committee members represent different geographic regions, sexes, ethnicities, races, intellectual perspectives/biases, and scopes of clinical practice. The Task Force may also invite organizations and professional societies with related interests and expertise to participate as partners, collaborators, or endorsers.

Relationships With Industry and Other Entities
The ACC and AHA have rigorous policies and methods to ensure that guidelines are developed without bias or improper influence. The complete relationships with industry and other entities (RWI) policy can be found at http://www.acc.org/guidelines/about-guidelines-and-clinical-documents/relationships-with-industry-policy. Appendix 1 of the present document lists writing committee members’ relevant RWI. For the purposes of full transparency, writing committee members’ comprehensive disclosure information is available online (http://hyper.ahajournals.org/lookup/suppl/doi:10.1161/HYP.0000000000000065/-/DC1). Comprehensive disclosure information for the Task Force is available at http://www.acc.org/guidelines/about-guidelines-and-clinical-documents/guidelines-and-documents-task-forces.

Evidence Review and Evidence Review Committees
In developing recommendations, the writing committee uses evidence-based methodologies that are based on all available data (6-9). Literature searches focus on randomized controlled trials (RCTs) but also include registries, nonrandomized comparative and descriptive studies, case series, cohort studies, systematic reviews, and expert opinion. Only key references are cited.

An independent evidence review committee (ERC) is commissioned when there are 1 or more questions deemed of utmost clinical importance that merit formal systematic review. The systematic review will determine which patients are most likely to benefit from a drug, device, or treatment strategy and to what degree. Criteria for commissioning an ERC and formal systematic review include: a) the absence of a current authoritative systematic review, b) the feasibility of defining the benefit and risk in a time frame consistent with the writing of a guideline, c) the relevance to a substantial number of patients, and d) the likelihood that the findings can be translated into actionable recommendations. ERC members may include methodologists, epidemiologists, healthcare providers, and biostatisticians. The recommendations developed by the writing committee on the basis of the systematic review are marked with “SR”.

Whelton PK, et al.
2017 High Blood Pressure Clinical Practice Guideline
Guideline-Directed Management and Therapy
The term guideline-directed management and therapy (GDMT) encompasses clinical evaluation, diagnostic testing, and pharmacological and procedural treatments. For these and all recommended drug treatment regimens, the reader should confirm the dosage by reviewing product insert material and evaluate the treatment regimen for contraindications and interactions. The recommendations are limited to drugs, devices, and treatments approved for clinical use in the United States.

Class of Recommendation and Level of Evidence
The Class of Recommendation (COR) indicates the strength of the recommendation, encompassing the estimated magnitude and certainty of benefit in proportion to risk. The Level of Evidence (LOE) rates the quality of scientific evidence that supports the intervention on the basis of the type, quantity, and consistency of data from clinical trials and other sources (Table 1) (6-8).

COR and LDE are determined independently (any COR may be paired with any LDE).

A recommendation with LDE C does not imply that the recommendation is weak. Many important clinical questions addressed in guidelines do not lend themselves to clinical trials. Although RCTs are unavailable, there may be a very clear clinical consensus that a particular test or therapy is useful or effective.

* The outcome or result of the intervention should be specified (an improved clinical outcome or increased diagnostic accuracy or incremental prognostic information).

‡ For comparative-effectiveness recommendations (COR I and IIa; LDE A and B only), studies that support the use of comparator were should involve direct comparisons of the treatments or strategies being evaluated.

The method of assessing quality is evolving, including the application of standardized, widely used, and preferably validated evidence grading tools; and for systematic reviews, the incorporation of an Evidence Review Committee.

COR indicates Class of Recommendation; EO, expert opinion; LD, limited data; LDE, Level of Evidence; NR, nonrandomized; R, randomized; and RCT, randomized controlled trial.

References
1. Introduction

As early as the 1920s, and subsequently in the 1959 Build and Blood Pressure Study (1) of almost 5 million adults insured between 1934 and 1954, a strong direct relationship was noted between level of BP and risk of clinical complications and death. In the 1960s, these findings were confirmed in a series of reports from the Framingham Heart Study (2). The 1967 and 1970 Veterans Administration Cooperative Study Group reports ushered in the era of effective treatment for high BP (3, 4). The first comprehensive guideline for detection, evaluation, and management of high BP was published in 1977, under the sponsorship of the NHLBI (5). In subsequent years, a series of Joint National Committee (JNC) BP guidelines were published to assist the practice community and improve prevention, awareness, treatment, and control of high BP (5-7). The present guideline updates prior JNC reports.

1.1. Methodology and Evidence Review

An extensive evidence review, which included literature derived from research involving human subjects, published in English, and indexed in MEDLINE (through PubMed), EMBASE, the Cochrane Library, the Agency for Healthcare Research and Quality, and other selected databases relevant to this guideline, was conducted between February and August 2015. Key search words included but were not limited to the following: adherence; aerobic; alcohol intake; ambulatory care; antihypertensive: agents, drug, medication, therapy; beta adrenergic blockers; blood pressure: arterial, control, determination, devices, goal, high, improve, measurement, monitoring, ambulatory; calcium channel blockers; diet; diuretic agent; drug therapy; heart failure: diastolic, systolic; hypertension: white coat, masked, ambulatory, isolated ambulatory, isolated clinic, diagnosis, reverse white coat, prevention, therapy, treatment, control;
intervention; lifestyle: measures, modification; office visits; patient outcome; performance measures; physical activity; potassium intake; protein intake; renin inhibitor; risk reduction: behavior, counseling; screening; sphygmomanometers; spironolactone; therapy; treatment: adherence, compliance, efficacy, outcome, protocol, regimen; weight. Additional relevant studies published through June 2016, during the guideline writing process, were also considered by the writing committee and added to the evidence tables when appropriate. The final evidence tables included in the Online Data Supplement (http://hyper.ahajournals.org/lookup/suppl/doi:10.1161/HYP.0000000000000065/-/DC2) summarize the evidence used by the writing committee to formulate recommendations.

As noted in the preamble, an independent ERC was commissioned to perform a formal systematic review of 4 critical clinical questions related to hypertension (Table 2), the results of which were considered by the writing committee for incorporation into this guideline. Concurrent with this process, writing committee members evaluated other published data relevant to the guideline. The findings of the ERC and the writing committee members were formally presented and discussed, and then guideline recommendations were developed. The systematic review report, “Systematic Review for the 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults,” is published in conjunction with this guideline (8), and its respective data supplements are available online (http://hyper.ahajournals.org/lookup/suppl/doi:10.1161/HYP.0000000000000067/-/DC2). No writing committee member reported a RWI. Drs. Whelton, Wright, and Williamson had leadership roles in SPRINT (Systolic Blood Pressure Intervention Trial). Dr. Carey chaired committee discussions in which the SPRINT results were considered.

BP indicates blood pressure.

1.2. Organization of the Writing Committee

The writing committee consisted of clinicians, cardiologists, epidemiologists, internists, an endocrinologist, a geriatrician, a nephrologist, a neurologist, a nurse, a pharmacist, a physician assistant, and 2 lay/patient representatives. It included representatives from the ACC, AHA, American Academy of Physician Assistants (AAPA), Association of Black Cardiologists (ABC), American College of Preventive Medicine (ACPM), American Geriatrics Society (AGS), American Pharmacists Association (APhA), American
1.3. Document Review and Approval

This document was reviewed by 2 official reviewers nominated by the ACC and AHA; 1 reviewer each from the AAPA, ABC, ACPM, AGS, APhA, ASH, ASPC, NMA, and PCNA; and 38 individual content reviewers. Reviewers’ RWI information was distributed to the writing committee and is published in this document (Appendix 2).

This document was approved for publication by the governing bodies of the ACC, AHA, AAPA, ABC, ACPM, AGS, APhA, ASH, ASPC, NMA, and PCNA.

1.4. Scope of the Guideline

The present guideline is intended to be a resource for the clinical and public health practice communities. It is designed to be comprehensive but succinct and practical in providing guidance for prevention, detection, evaluation, and management of high BP. It is an update of the NHLBI publication, “The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure” (JNC 7) (7). It incorporates new information from studies of office-based BP-related risk of CVD, ambulatory blood pressure monitoring (ABPM), home blood pressure monitoring (HBPM), telemedicine, and various other areas. This guideline does not address the use of BP-lowering medications for the purposes of prevention of recurrent CVD events in patients with stable ischemic heart disease (SIHD) or chronic heart failure (HF) in the absence of hypertension; these topics are the focus of other ACC/AHA guidelines (9, 10). In developing the present guideline, the writing committee reviewed prior published guidelines, evidence reviews, and related statements. Table 3 contains a list of publications and statements deemed pertinent to this writing effort and is intended for use as a resource, thus obviating the need to repeat existing guideline recommendations.

2. BP and CVD Risk

2.1. Observational Relationship

Observational studies have demonstrated graded associations between higher systolic blood pressure (SBP) and diastolic blood pressure (DBP) and increased CVD risk (1, 2). In a meta-analysis of 61 prospective studies, the risk of CVD increased in a log-linear fashion from SBP levels <115 mm Hg to >180 mm Hg and from DBP levels <75 mm Hg to >105 mm Hg (1). In that analysis, 20 mm Hg higher SBP and 10 mm Hg higher DBP were each associated with a doubling in the risk of death from stroke, heart disease, or other vascular disease. In a separate observational study including >1 million adult patients ≥30 years of age, higher SBP and DBP were associated with increased risk of CVD incidence and angina, myocardial infarction (MI), HF, stroke, peripheral artery disease (PAD), and abdominal aortic aneurysm, each evaluated separately (2). An increased risk of CVD associated with higher SBP and DBP has been reported across a broad age spectrum, from 30 years to >80 years of age. Although the relative risk of incident CVD associated with higher SBP and DBP is smaller at older ages, the corresponding high BP–related increase in absolute risk is larger in older persons (≥65 years) given the higher absolute risk of CVD at an older age (1).

References

2.2. BP Components

Epidemiological studies have evaluated associations of SBP and DBP, as well as derived components of BP measurements (including pulse pressure, mean BP, and mid-BP), with CVD outcomes (Table 4). When considered separately, higher levels of both SBP and DBP have been associated with increased CVD risk (1, 2). Higher SBP has consistently been associated with increased CVD risk after adjustment for, or within strata of, DBP (3-5). In contrast, after consideration of SBP through adjustment or stratification, DBP has not been consistently associated with CVD risk (6, 7). Although pulse pressure and mid-BP have been associated with increased CVD risk independent of SBP and DBP in some studies, SBP (especially) and DBP are prioritized in the present document because of the robust evidence base for these measures in both observational studies and clinical trials and because of their ease of measurement in practice settings (8-11).

2.3. Population Risk

In 2010, high BP was the leading cause of death and disability-adjusted life years worldwide (1, 2). In the United States, hypertension (see Section 3.1 for definition) accounted for more CVD deaths than any other modifiable CVD risk factor and was second only to cigarette smoking as a preventable cause of death for any reason (3). In a follow-up study of 23,272 U.S. NHANES (National Health and Nutrition Examination Survey) participants, >50% of deaths from coronary heart disease (CHD) and stroke occurred among individuals with hypertension (4). Because of the high prevalence of hypertension and its associated increased risk of CHD, stroke, and end-stage renal disease (ESRD), the population-attributable risk of these outcomes associated with hypertension is high (4, 5). In the population-based ARIC (Atherosclerosis Risk in Communities) study, 25% of the cardiovascular events (CHD, coronary revascularization, stroke, or HF) were attributable to hypertension. In the Northern Manhattan study, the percentage of events attributable to hypertension was higher in women (32%) than in men (19%) and higher in blacks (36%) than in whites (21%) (6). In 2012, hypertension was the second leading assigned cause of ESRD, behind diabetes mellitus (DM), and accounted for 34% of incident ESRD cases in the U.S. population (7).

</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>B-NR</td>
<td>1. Screening for and management of other modifiable CVD risk factors are recommended in adults with hypertension (1, 2).</td>
</tr>
</tbody>
</table>

Synopsis

Many adult patients with hypertension have other CVD risk factors; a list of such modifiable and relatively fixed risk factors is provided in Table 5. Among U.S. adults with hypertension between 2009 and 2012, 15.5% were current smokers, 49.5% were obese, 63.2% had hypercholesterolemia, 27.2% had DM, and 15.8% had chronic kidney disease (CKD; defined as estimated glomerular filtration rate [eGFR] <60 mL/min/1.73 m² and/or urine albumin:creatinine ≥300 mg/g) (3).

Not only are CVD risk factors common among adults with hypertension, a higher percentage of adults with CVD risk factors have hypertension. For example, 71% of U.S. adults with diagnosed DM have hypertension (4). In the Chronic Renal Insufficiency Cohort (CRIC), 86% of the participants had hypertension (5). Also, 28.1% of adults with hypertension and CKD in the population-based REGARDS (Reasons for Geographic and Racial Differences in Stroke) study had apparent resistant hypertension (6). In NHANES 1999–2010, 35.7% of obese individuals had hypertension (7). The presence of multiple CVD risk factors in individuals with hypertension results in high absolute risks for CHD and stroke in this population. For example, among U.S. adults with hypertension between 2009 and 2012, 41.7% had a 10-year CHD risk >20%, 40.9% had a risk of 10% to 20%, and only 18.4% had a risk <10% (3).

Modifiable risk factors for CVD that are common among adults with hypertension include cigarette smoking/tobacco smoke exposure, DM, dyslipidemia (including high levels of low-density lipoprotein cholesterol or hypercholesterolemia, high levels of triglycerides, and low levels of high-density lipoprotein cholesterol), overweight/obesity, physical inactivity/low fitness level, and unhealthy diet (8). The relationship between hypertension and other modifiable risk factors is complex and interdependent, with several sharing mechanisms of action and pathophysiology. CVD risk factors affect BP through over activation of the renin-angiotensin-aldosterone system, activation of the sympathetic nervous system, inhibition of the cardiac natriuretic peptide system, endothelial dysfunction, and other mechanisms (9-11). Treating some of the other modifiable risk factors may reduce BP through modification of shared pathology, and CVD risk may be reduced by treating global risk factor burden.
Observational studies have demonstrated that CVD risk factors frequently occur in combination, with ≥3 risk factors present in 17% of patients (1). A meta-analysis from 18 cohort studies involving 257,384 patients identified a lifetime risk of CVD death, nonfatal MI, and fatal or nonfatal stroke that was substantially higher in adults with ≥2 CVD risk factors than in those with only 1 risk factor (1, 2).

Synopsis

Although a continuous association exists between higher BP and increased CVD risk (see Section 2.1), it is useful to categorize BP levels for clinical and public health decision making. In the present document, BP is categorized into 4 levels on the basis of average BP measured in a healthcare setting (office pressures): normal, elevated, and stage 1 or 2 hypertension (Table 6). Online Data Supplement C illustrates schematically the SBP and DBP categories defining normal BP, elevated BP, and stages 1 and 2 hypertension. This categorization differs from that previously recommended in the JNC 7 report, with stage 1 hypertension now defined as an SBP of 130–139 or a DBP of 80–89 mm Hg, and with stage 2 hypertension in the present document corresponding to stages 1 and 2 in the JNC 7 report (21). The rationale for this categorization is based on observational data related to the association between SBP/DBP and CVD risk, RCTs of lifestyle modification to lower BP, and RCTs of treatment with antihypertensive medication to prevent CVD. The increased risk of CVD among adults with stage 2 hypertension is well established. An increasing number of individual studies and meta-analyses of observational data have reported a gradient of progressively higher CVD risk going from normal BP to elevated BP and stage 1 hypertension (4-10, 12, 13, 16). In many of these meta-analyses, the hazard ratios for CHD and stroke were between 1.1 and 1.5 for the comparison of SBP/DBP of 120–129/80–84 mm Hg versus <120/80 mm Hg, and between 1.5 and 2.0 for the comparison of SBP/DBP of 130–139/85–89 mm Hg versus <120/80 mm Hg. This risk gradient was consistent across subgroups defined by sex and race/ethnicity. The relative increase in CVD risk associated with higher BP was attenuated but still present among older adults (1). The prevalence of severe hypertension has been declining over time, but approximately 12.3% of U.S. adults with hypertension have an average SBP ≥160 mm Hg or average DBP ≥100 mm Hg (22). Lifestyle modification and pharmaceutical antihypertensive treatment recommendations for individuals with elevated BP and stages 1 and 2 hypertension are provided in Sections 6 and 8, respectively. The relationship of this classification schema with measurements obtained by ambulatory BP recording and home BP measurements is discussed in Section 4.2.

Recommendation-Specific Supportive Text

1. As was the case in previous BP classification systems, the choice and the naming of the categories were based on a pragmatic interpretation of BP-related CVD risk and benefit of BP reduction in clinical trials. Meta-analyses of observational studies have demonstrated that elevated BP and hypertension are associated with increased risk of CVD, ESRD, subclinical atherosclerosis, and all-cause death (1-17). The recommended BP classification system is most valuable in untreated adults as an aid in decisions about prevention or treatment of high BP. However, it is also useful in assessing the success of interventions to reduce BP.

References
3.2. Lifetime Risk of Hypertension

Observational studies have documented a relatively high incidence of hypertension over periods of 5 to 10 years of follow-up (1, 2). Thus, there is a much higher long-term population burden of hypertension as BP progressively increases with age. Several studies have estimated the long-term cumulative incidence of developing hypertension (3, 4). In an analysis of 1132 white male medical students (mean age: approximately 23 years at baseline) in the Johns Hopkins Precursors study, 0.3%, 6.5%, and 37% developed hypertension at age 25, 45, and 65 years, respectively (5). In MESA (Multi-Ethnic Study of Atherosclerosis), the percentage of the population developing hypertension over their lifetimes was higher for African Americans and Hispanics than for whites and Asians (3). For adults 45 years of age without hypertension, the 40-year risk of developing hypertension was 93% for African-American, 92% for Hispanic, 86% for white, and 84% for Chinese adults (3). In the Framingham Heart Study, approximately 90% of adults free of hypertension at age 55 or 65 years developed hypertension during their lifetimes (4). All of these estimates were based on use of the 140/90–mm Hg cutpoint for recognition of hypertension and would have been higher had the 130/80–mm Hg cutpoint been used.

References

3.3. Prevalence of High BP

Prevalence estimates are greatly influenced by the choice of cutpoints to categorize high BP, the methods used to establish the diagnosis, and the population studied (1, 2). Most general population prevalence estimates are derived from national surveys. Table 7 provides estimates for prevalence of hypertension in the U.S. general adult population (≥20 years of age) that are based on the definitions of hypertension recommended in the present guideline and in the JNC 7 report. The prevalence of hypertension among U.S. adults is substantially higher when the definition in the present guideline is used versus the JNC 7 definition (46% versus 32%). However, as described in Section 8.1, nonpharmacological treatment (not antihypertensive medication) is recommended for most U.S. adults who have hypertension as defined in the present guideline but who would not meet the JNC 7 definition for hypertension. As a consequence, the new definition results
in only a small increase in the percentage of U.S. adults for whom antihypertensive medication is recommended in conjunction with lifestyle modification.

The prevalence of hypertension rises dramatically with increasing age and is higher in blacks than in whites, Asians, and Hispanic Americans. NHANES estimates of JNC 7–defined hypertension prevalence have remained fairly stable since the early 2000s (1). Most contemporary population surveys, including NHANES, rely on an average of BP measurements obtained at a single visit (2), which is likely to result in an overestimate of hypertension prevalence compared with what would be found by using an average of ≥2 readings taken on ≥2 visits (1), as recommended in current and previous BP guidelines (3-5). The extent to which guideline recommendations for use of BP averages from ≥2 occasions is followed in practice is unclear. Adding self-report of previously diagnosed hypertension yields a 5% to 10% higher estimate of prevalence (1, 6, 7). Most individuals who were added by use of this expanded definition have been diagnosed as having hypertension by a health professional on >1 occasion, and many have been advised to change their lifestyle (2, 6).

References
3.4. Awareness, Treatment, and Control

Prevalence estimates for awareness, treatment, and control of hypertension are usually based on self-reports of the hypertension diagnosis (awareness), use of BP-lowering medications in those with hypertension (treatment), and achievement of a satisfactory SBP/DBP during treatment of hypertension (control). Before the present publication, awareness and treatment in adults were based on the SBP/DBP cutpoints of 140/90 mm Hg, and control was based on an SBP/DBP <140/90 mm Hg. In the U.S. general adult population, hypertension awareness, treatment, and control have been steadily improving since the 1960s (1-4), with NHANES 2009 to 2012 prevalence estimates for men and women, respectively, being 80.2% and 85.4% for awareness, 70.9% and 80.6% for treatment (88.4% and 94.4% in those who were aware), 69.5% and 68.5% for control in those being treated, and 49.3% and 55.2% for overall control in adults with hypertension (5). The NHANES experience may underestimate awareness, treatment, and control of hypertension because it is based on BP estimates derived from an average of readings obtained at a single visit, whereas guidelines recommend use of BP averages of ≥2 readings obtained on ≥2 occasions. In addition, the current definition of control excludes the possibility of control resulting from lifestyle change or nonpharmacological interventions. NHANES hypertension control rates have been consistently higher in women than in men (55.3% versus 38.0% in 2009–2012); in whites than in blacks and Hispanics (41.3% versus 31.1% and 23.6%, respectively, in men, and 57.2% versus 43.2% and 52.9%, respectively, in women, for 2009–2012); and in older than in younger adults (50.5% in adults ≥60 years of age versus 34.4% in patients 18 to 39 years of age for 2011–2012) up to the seventh decade (4, 5), although control rates are considerably lower for those ≥75 years (46%) and only 39.8% for adults ≥80 years (6). In addition, control rates are higher for persons of higher socioeconomic status (43.2% for adults with an income >400% above the U.S. government poverty line versus 30.2% for those below this line in 2003 to 2006) (5). Research studies have repeatedly demonstrated that structured, goal-oriented BP treatment initiatives with feedback and provision of free medication result in a substantial improvement in BP control (7-9). Control rates that are much higher than noted in the general population have been reported in care settings where a systems approach (detailed in Sections 12.2 and 12.3) has been implemented for insured adults (10-12).

4. Measurement of BP

4.1. Accurate Measurement of BP in the Office

<table>
<thead>
<tr>
<th>Recommendation for Accurate Measurement of BP in the Office</th>
</tr>
</thead>
<tbody>
<tr>
<td>COR</td>
</tr>
<tr>
<td>I</td>
</tr>
</tbody>
</table>

Synopsis

Although measurement of BP in office settings is relatively easy, errors are common and can result in a misleading estimation of an individual’s true level of BP. There are various methods for measuring BP in the office. The clinical standard of auscultatory measures calibrated to a column of mercury has given way to oscillometric devices (in part because of toxicological issues with mercury). Oscillometric devices use a sensor that detects oscillations in pulsatile blood volume during cuff inflation and deflation. BP is indirectly calculated from maximum amplitude algorithms that involve population-based data. For this reason, only devices with a validated measurement protocol can be recommended for use (see Section 4.2 for additional details). Many of the newer oscillometric devices automatically inflate multiple times (in 1- to 2-minute intervals), allowing patients to be alone and undisturbed during measurement. Although much of the available BP-related risk information and antihypertensive treatment trial experience have been generated by using “traditional” office methods of BP measurement, there is a growing evidence base supporting the use of automated office BP measurements (1).

Recommendation-Specific Supportive Text

1. Accurate measurement and recording of BP are essential to categorize level of BP, ascertain BP-related CVD risk, and guide management of high BP. Most systematic errors in BP measurement can be avoided by following the suggestions provided in Table 8, including having the patient sit quietly for 5 minutes before a reading is taken, supporting the limb used to measure BP, ensuring the BP cuff is at heart level, using the correct cuff size (Table 9), and, for auscultatory readings, deflating the cuff slowly (2). In those who are already taking medication that affects BP, the timing of BP measurements in relation to ingestion of the patient’s medication should be standardized. Because individual BP measurements tend to vary in an unpredictable or random fashion, a single reading is inadequate for clinical decision-making. An average of 2 to 3 BP measurements obtained on 2 to 3 separate occasions will minimize random error and provide a more accurate basis for estimation of BP. In addition to clinicians, other caregivers and patients who perform BP self-monitoring should be trained to follow the checklist in Table 8. Common errors in clinical practice that can lead to inaccurate estimation of BP include failure to allow for a rest period and/or talking with the patient during or immediately before the recording, improper patient positioning (e.g., sitting or lying on an examination table), rapid cuff deflation (for auscultatory readings), and reliance on BPs measured at a single occasion.

<tr>
<th>Key Steps for Proper BP Measurements</th>
<th>Specific Instructions</th>
</tr>
</thead>
</table>
| **Step 1: Properly prepare the patient** | 1. Have the patient relax, sitting in a chair (feet on floor, back supported) for >5 min.  
2. The patient should avoid caffeine, exercise, and smoking for at least 30 min before measurement.  
3. Ensure patient has emptied his/her bladder.  
4. Neither the patient nor the observer should talk during the rest period or during the measurement.  
5. Remove all clothing covering the location of cuff placement.  
6. Measurements made while the patient is sitting or lying on an examining table do not fulfill these criteria. |
| **Step 2: Use proper technique for BP measurements** | 1. Use a BP measurement device that has been validated, and ensure that the device is calibrated periodically.*  
2. Support the patient’s arm (e.g., resting on a desk).  
3. Position the middle of the cuff on the patient’s upper arm at the level of the right atrium (the midpoint of the sternum).  
4. Use the correct cuff size, such that the bladder encircles 80% of the arm, and note if a larger- or smaller-than-normal cuff size is used (Table 9).  
5. Either the stethoscope diaphragm or bell may be used for auscultatory readings (5, 6). |
| **Step 3: Take the proper measurements needed for diagnosis and treatment of elevated BP/hypertension** | 1. At the first visit, record BP in both arms. Use the arm that gives the higher reading for subsequent readings.  
2. Separate repeated measurements by 1–2 min.  
3. For auscultatory determinations, use a palpated estimate of radial pulse obliteration pressure to estimate SBP. Inflate the cuff 20–30 mm Hg above this level for an auscultatory determination of the BP level.  
4. For auscultatory readings, deflate the cuff pressure 2 mm Hg per second, and listen for Korotkoff sounds. |
| **Step 4: Properly document accurate BP readings** | 1. Record SBP and DBP. If using the auscultatory technique, record SBP and DBP as onset of the first Korotkoff sound and disappearance of all Korotkoff sounds, respectively, using the nearest even number.  
2. Note the time of most recent BP medication taken before measurements. |
| **Step 5: Average the readings** | Use an average of ≥2 readings obtained on ≥2 occasions to estimate the individual’s level of BP. |
| **Step 6: Provide BP readings to patient** | Provide patients the SBP/DBP readings both verbally and in writing. |

*See Section 4.2 for additional guidance.

Synopsis

Out-of-office measurement of BP can be helpful for confirmation and management of hypertension. Self-monitoring of BP refers to the regular measurement of BP by an individual at home or elsewhere outside the clinic setting. Among individuals with hypertension, self-monitoring of BP, without other interventions, has shown limited evidence for treatment-related BP reduction and achievement of BP control (1, 5, 6). However, with the increased recognition of inconsistencies between office and out-of-office BPs (see Section 4.4) and greater reduction in BP being recommended for hypertension control, increased attention is being paid to out-of-office BP readings. Although APBM is generally accepted as the best out-of-office measurement method, HBPM is often a more practical approach in clinical practice. Recommended procedures for the collection of HBPM data are provided in Table 10. If self-monitoring is used, it is important to ensure that the BP measurement device used has been validated with an internationally accepted protocol and the results have been published in a peer-reviewed journal (7). A guide to the relationship between HBPM BP readings...
and corresponding readings obtained in the office and by ABPM is presented in Table 11. The precise relationships between office readings, ABPM, and HBPM are unsettled, but there is general agreement that office BPs are often higher than ABPM or HBPM BPs, especially at higher BPs.

**Recommendation-Specific Supportive Text**

1. Ambulatory BP monitoring (ABPM) is used to obtain out-of-office BP readings at set intervals, usually over a period of 24 hours. Home BP monitoring (HBPM) is used to obtain a record of out-of-office BP readings taken by a patient. Both ABPM and HBPM typically provide BP estimates that are based on multiple measurements. A systematic review conducted by the U.S. Preventive Services Task Force reported that ABPM provided a better method to predict long-term CVD outcomes than did office BPs. It incorporates new information from studies of home blood pressure monitoring (HBPM), ambulatory blood pressure monitoring (ABPM), the relationship of overall CVD risk to the effectiveness of blood pressure lowering, clinical outcomes related to different blood pressure goals, strategies to improve blood pressure control and various other areas. A small body of evidence suggested, but did not confirm, that HBPM could serve as a similar predictor of outcomes (4). Meta-analyses of RCTs have identified clinically useful reductions in SBP and DBP and achievement of BP goals at 6 months and 1 year when self-monitoring of BP has been used in conjunction with other interventions, compared with usual care. Meta-analyses of RCTs have identified only small net reductions in SBP and DBP at 6 months and 1 year for use of self-monitoring of BP on its own, as compared with usual care (1, 5, 6). See Section 4.4 for additional details of diagnostic classification and Section 12 for additional details of telehealth and out-of-office BP measurement for management of high BP.

### 4.3. Ambulatory BP Monitoring

All of the major RCTs have been based on use of clinic BP readings. However, ABPM is often used to supplement BP readings obtained in office settings (1). The monitors are usually programmed to obtain readings every 15 to 30 minutes throughout the day and every 15 minutes to 1 hour during the night. ABPM is conducted while individuals go about their normal daily activities. ABPM can a) provide estimates of mean BP over the entire monitoring period and separately during nighttime and daytime, b) determine the daytime-to-nighttime BP ratio to identify the extent of nocturnal “dipping,” c) identify the early-morning BP surge pattern, d) estimate BP variability, and e) allow for recognition of symptomatic hypotension. The U.S. Centers for Medicaid & Medicare Services and other agencies provide reimbursement for ABPM in patients with...
suspected white coat hypertension (2). Medicare claims for ABPM between 2007 and 2010 were reimbursed at a median of $52 and were submitted for <1% of beneficiaries (3, 4). A list of devices validated for ABPM is available (5, 6).

ABPM and HBPM definitions of high BP use different BP thresholds than those used by the previously mentioned office-based approach to categorize high BP identified in Section 3.1. Table 11 provides best estimates for corresponding home, daytime, nighttime, and 24-hour ambulatory levels of BP, including the values recommended for identification of hypertension with office measurements. Typically, a clinic BP of 140/90 mm Hg corresponds to home BP values of 135/85 mm Hg and to ABPM values defined as a daytime SBP/DBP of 135/85 mm Hg, a nighttime SBP/DBP of 120/70 mm Hg, and a 24-hour SBP/DBP of 130/80 mm Hg (7, 8). These thresholds are based on data from European, Australian, and Asian populations, with few data available for establishing appropriate thresholds for U.S. populations (9-13). They are provided as a guide but should be interpreted with caution. Higher daytime SBP measurements from ABPM can be associated with an increased risk of CVD and all-cause death independent of clinic-measured BP (14). A meta-analysis of observational studies that included 13,844 individuals suggested nighttime BP is a stronger risk factor for CHD and stroke than either clinic or daytime BP (15).

Methodological issues complicate the interpretation of data from studies that report office and out-of-office BP readings. Definitions and diagnostic methods for identifying white coat hypertension and masked hypertension (see Section 4.4) have not been standardized. The available studies have differed with regard to number of office readings obtained, use of 24-hour ABPM, use of daytime-only ABPM, inclusion of daytime and nighttime BP readings as separate categories, HBPM for monitoring out-of-office BP levels, and even the BP thresholds used to define hypertension with ABPM or HBPM readings. In addition, there are few data that address reproducibility of these hypertension profiles over time, with several studies suggesting progression of white coat hypertension and especially of masked hypertension to sustained office-measured hypertension (16-22).

ABPM indicates ambulatory blood pressure monitoring; and BP, blood pressure.

Synopsis

The availability of noninvasive BP monitoring techniques has resulted in differentiation of hypertension into several clinically useful categories that are based on the place of BP measurement (Table 12) (1, 13, 14). These include masked hypertension and white coat hypertension, in addition to sustained hypertension. White coat hypertension is characterized by elevated office BP but normal readings when measured outside the office with either ABPM or HBPM. In contrast, masked hypertension is characterized by office readings suggesting normal BP but out-of-office (ABPM/HBPM) readings that are consistently above normal (15). In sustained hypertension, BP readings are elevated in both office and out-of-office settings.

In patients treated for hypertension, both “white coat effect” (higher office BPs than out-of-office BPs) and “masked uncontrolled hypertension” (controlled office BPs but uncontrolled BPs in out-of-office settings) categories have been reported (5, 15, 16). The white coat effect (usually considered clinically significant when office SBP/DBPs are >20/10 mm Hg higher than home or ABPM SBP/DBPs) has been implicated in “pseudo-resistant hypertension” (see Section 11.1) and results in an underestimation of office BP control rates (17, 18).

The prevalence of masked hypertension varies from 10% to 26% (mean 13%) in population-based surveys and from 14% to 30% in normotensive clinic populations (6, 16, 19-21).

The risk of CVD and all-cause mortality in persons with masked hypertension is similar to that noted in those with sustained hypertension and about twice as high as the corresponding risk in their normotensive counterparts (3, 4, 6, 8, 11). The prevalence of masked hypertension increases with higher office BP readings (20, 22, 23).

The prevalence of white coat hypertension is higher with increasing age (24), female versus male sex, nonsmoking versus current smoking status, and routine office measurement of BP by clinician observers versus unattended BP measurements. Many, but not all, studies (4, 6, 8, 25, 26) have identified a minimal increase in risk of CVD complications or all-cause mortality in patients who have white coat hypertension. This has resulted in a recommendation by some panels to screen for white coat hypertension with ABPM (or HBPM) to avoid initiating antihypertensive drug treatment in such individuals (2, 5, 27). The white coat effect and masked uncontrolled hypertension appear to follow the risk profiles of their white coat hypertension and masked hypertension counterparts, respectively (3, 12).

There are no data on the risks and benefits of treating white coat and masked hypertension. Despite these methodological differences, the data are consistent in indicating that masked hypertension and masked uncontrolled hypertension are associated with an increased prevalence of target organ damage and risk of CVD, stroke, and mortality compared with normotensive individuals and those with white coat hypertension.

Figure 1 is an algorithm on the detection of white coat hypertension or masked hypertension in patients not on drug therapy. Figure 2 is an algorithm on detection of white coat effect or masked uncontrolled hypertension in patients on drug therapy. Table 12 is a summary of BP patterns based on office and out-of-office measurements.
Recommendation-Specific Supportive Text

1. White coat hypertension prevalence averages approximately 13% and as high as 35% in some hypertensive populations (1, 2), and ABPM and HBPM are better predictors of CVD risk due to elevated BP than are office BP measurements, with ABPM being the preferred measurement option. The major clinical relevance of white coat hypertension is that it has typically been associated with a minimal to only slightly increased risk of CVD and all-cause mortality risk (3, 4, 7, 11, 24). If ABPM resources are not readily available, HBPM provides a reasonable but less desirable alternative to screen for white coat hypertension, although the overlap with ABPM is only 60% to 70% for detection of white coat hypertension (5, 9, 27-30).

2. The incidence of white coat hypertension converting to sustained hypertension (justifying the addition of antihypertensive drug therapy to lifestyle modification) is 1% to 5% per year by ABPM or HBPM, with a higher incidence of conversion in those with elevated BP, older age, obesity, or black race (2, 7).

3. The overlap between HBPM and both daytime and 24-hour ABPM in diagnosing white coat hypertension is only 60% to 70%, and the data for prediction of CVD risk are stronger with ABPM than with office measurements (5, 9, 27-30). Because a diagnosis of white coat hypertension may result in a decision not to treat or intensify treatment in patients with elevated office BP readings, confirmation of BP control by ABPM in addition to HBPM provides added support for this decision.

4. In contrast to white coat hypertension, masked hypertension is associated with a CVD and all-cause mortality risk twice as high as that seen in normotensive individuals, with a risk range similar to that of patients with sustained hypertension (3, 4, 6, 8, 11, 31). Therefore, out-of-office readings are reasonable to confirm BP control seen with office readings.

5. The white coat effect has been implicated in office-measured uncontrolled hypertension and pseudo-resistant hypertension, which may result in BP control being underestimated when subsequently assessed by ABPM (17, 18). The risk of vascular complications in patients with office-measured uncontrolled hypertension with a white coat effect is similar to the risk in those with controlled hypertension (3, 4, 7, 11, 12). White coat hypertension and white coat effect raise the concern that unnecessary antihypertensive drug therapy may be initiated or intensified. Because a diagnosis of white coat hypertension or white coat effect would result in a decision not to treat elevated office BP readings, confirmation of BP control by ABPM (or HBPM) provides more definitive support for the decision not to initiate antihypertensive drug therapy or accelerate treatment.

6. Analogous to masked hypertension in untreated patients, masked uncontrolled hypertension is defined in treated patients with hypertension by office readings suggesting adequate BP control but out-of-office readings (HBPM) that remain consistently above goal (3, 15, 16, 32, 33). The CVD risk profile for masked uncontrolled hypertension appears to follow the risk profile for masked hypertension (3, 12, 34). Although the evidence is consistent in identifying the increased risk of masked uncontrolled hypertension, evidence is lacking on whether the treatment of masked hypertension or masked uncontrolled hypertension reduces clinical outcomes. A suggestion for assessing CVD risk is provided in Section 8.

7. Although both ABPM and HBPM are better predictors of CVD risk than are office BP readings, ABPM confirmation of elevated BP by HBPM might be reasonable because of the more extensive documentation of CVD risk with ABPM. However, unlike the documentation of a significant white coat effect to justify the decision to not treat an elevated clinic BP, it is not mandatory to confirm masked uncontrolled hypertension determined by HBPM.

5. Causes of Hypertension

5.1. Genetic Predisposition

Hypertension is a complex polygenic disorder in which many genes or gene combinations influence BP (1, 2). Although several monogenic forms of hypertension have been identified, such as glucocorticoid-remediable aldosteronism, Liddle’s syndrome, Gordon’s syndrome, and others in which single-gene mutations fully explain the pathophysiology of hypertension, these disorders are rare (3). The current tabulation of known genetic variants contributing to BP and hypertension includes more than 25 rare mutations and 120 single-nucleotide polymorphisms (3, 4). However, even with the discovery of multiple single-nucleotide polymorphisms influencing control of BP since completion of the Human Genome Project in 2003, the associated variants have only small effects. Indeed, at present, the collective effect of all BP loci identified through genome-wide association studies accounts for only about 3.5% of BP variability (4). The presence of a high number of small-effect alleles associated with higher BP results in a more rapid increase in BP with age (5). Future studies will need to better elucidate genetic expression, epigenetic effects, transcriptomics, and proteomics that link genotypes with underlying pathophysiological mechanisms.

References

5.2. Environmental Risk Factors

Various environmental exposures, including components of diet, physical activity, and alcohol consumption, influence BP. Many dietary components have been associated with high BP (1, 2). Some of the diet-related factors associated with high BP include overweight and obesity, excess intake of sodium, and insufficient intake of potassium, calcium, magnesium, protein (especially from vegetables), fiber, and fish fats. Poor diet, physical inactivity, and excess intake of alcohol, alone or in combination, are the underlying cause of a large proportion of hypertension. Gut microbiota have also been linked to hypertension, especially in experimental
Whelton PK, et al.
2017 High Blood Pressure Clinical Practice Guideline

animals. (3) Some of the best-proven environmental relationships with high BP are briefly reviewed below, and nonpharmacological interventions to lower BP are discussed in Section 6.2.

References

5.2.1. Overweight and Obesity

Insurance industry actuarial reports have identified a striking relationship between body weight and high BP (1) and a direct relationship between overweight/obesity and hypertension (2). Epidemiological studies, including the Framingham Heart Study (3) and the Nurses’ Health Study (4), have consistently identified a direct relationship between body mass index and BP that is continuous and almost linear, with no evidence of a threshold (5, 6). The relationship with BP is even stronger for waist-to-hip ratio and computed tomographic measures of central fat distribution (7). Attributable risk estimates from the Nurses’ Health Study suggest that obesity may be responsible for about 40% of hypertension, and in the Framingham Offspring Study, the corresponding estimates were even higher (78% in men and 65% in women) (8, 9). The relationship between obesity at a young age and change in obesity status over time is strongly related to future risk of hypertension. In combined data from 4 longitudinal studies begun in adolescence with repeat examination in young adulthood to early middle age, being obese continuously or acquiring obesity was associated with a relative risk of 2.7 for developing hypertension. Becoming normal weight reduced the risk of developing hypertension to a level similar to those who had never been obese (10).

5.2.2. Sodium Intake

Sodium intake is positively associated with BP in migrant (11), cross-sectional (12-14), and prospective cohort studies (15) and accounts for much of the age-related increase in BP (11, 16). In addition to the well-accepted and important relationship of dietary sodium with BP, excessive consumption of sodium is independently associated with an increased risk of stroke (17, 18), CVD (19), and other adverse outcomes (20). Certain groups with various demographic, physiological, and genetic characteristics tend to be particularly sensitive to the effects of dietary sodium on BP (21-23). Salt sensitivity is a quantitative trait in which an increase in sodium load disproportionately increases BP (21, 24). Salt sensitivity is especially common in blacks, older adults, and those with a higher level of BP or comorbidities such as CKD, DM, or the metabolic syndrome (25). In aggregate, these groups constitute more than half of all U.S. adults (26). Salt sensitivity may be a marker for increased CVD and all-cause mortality risk independently of BP (27, 28), and the trait has been demonstrated to be reproducible (29). Current techniques for recognition of salt sensitivity are impractical in routine clinical practice, so salt sensitivity is best considered as a group characteristic.

5.2.3. Potassium

Potassium intake is inversely related to BP in migrant (30), cross-sectional (13, 16, 31, 32), and prospective cohort (33) studies. It is also inversely related to stroke (34-36). A higher level of potassium seems to blunt the effect of sodium on BP (37), with a lower sodium–potassium ratio being associated with a lower level of BP than that noted for corresponding levels of sodium or potassium on their own (38). Likewise, epidemiological studies suggest that a lower sodium–potassium ratio may result in a reduced risk of CVD as compared with the pattern for corresponding levels of either cation on its own (39).
5.2.4. Physical Fitness

Epidemiological studies have demonstrated an inverse relationship between physical activity and physical fitness and level of BP and hypertension (40). Even modest levels of physical activity have been associated with a decrease in the risk of incident hypertension (41). In several observational studies, the relationship between physical activity and BP has been most apparent in white men (40). With the advent of electronic activity trackers and ABPM, it has become increasingly feasible to conduct studies that relate physical activity and BP (42). Physical fitness, measured objectively by graded exercise testing, attenuates the rise of BP with age and prevents the development of hypertension. In the CARDIA (Coronary Artery Risk Development in Young Adults) study (43), physical fitness measured at 18 to 30 years of age in the upper 2 deciles of an otherwise healthy population was associated with one third the risk of developing hypertension 15 years later, and one half the risk after adjustment for body mass index, as compared with the lowest quintile. Change in fitness assessed 7 years later further modified risk (43). In a cohort of men 20 to 90 years of age who were followed longitudinally for 3 to 28 years, higher physical fitness decreased the rate of rise in SBP over time and delayed the time to onset of hypertension (44).

5.2.5. Alcohol

The presence of a direct relationship between alcohol consumption and BP was first reported in 1915 (45) and has been repeatedly identified in contemporary cross-sectional and prospective cohort studies (46). Estimates of the contribution of alcohol consumption to population incidence and prevalence of hypertension vary according to level of intake. In the United States, it seems likely that alcohol may account for close to 10% of the population burden of hypertension (higher in men than in women). In contrast to its detrimental effect on BP, alcohol intake is associated with a higher level of high-density lipoprotein cholesterol and, within modest ranges of intake, a lower level of CHD than that associated with abstinence (35).

References

5.3. Childhood Risk Factors and BP Tracking

BP distribution in the general population increases with age. Multiple longitudinal studies have investigated the relationship of childhood BP to adult BP. A meta-analysis of 50 such studies showed correlation coefficients of about 0.38 for SBP and 0.28 for DBP, with BPs in the upper range of the pediatric distribution (particularly BPs obtained in adolescence) predicting hypertension in adulthood (1). Several factors, including genetic factors and development of obesity, increase the likelihood that a high childhood BP will lead to future hypertension (2). Premature birth is associated with a 4–mm Hg higher SBP and a 3–mm Hg higher DBP in adulthood, with somewhat larger effects in women than in men (3). Low birth weight from other causes also contributes to higher BP in later life (4).

Synopsis

A specific, remediable cause of hypertension can be identified in approximately 10% of adult patients with hypertension (1). If a cause can be correctly diagnosed and treated, patients with secondary hypertension can achieve a cure or experience a marked improvement in BP control, with reduction in CVD risk. All new patients with hypertension should be screened with a history, physical examination, and laboratory investigations, as recommended in Section 7, before initiation of treatment.

Secondary hypertension can underlie severe elevation of BP, pharmacologically resistant hypertension, sudden onset of hypertension, increased BP in patients with hypertension previously controlled...
on drug therapy, onset of diastolic hypertension in older adults, and target organ damage disproportionate to the duration or severity of the hypertension. Although secondary hypertension should be suspected in younger patients (<30 years of age) with elevated BP, it is not uncommon for primary hypertension to manifest at a younger age, especially in blacks (2), and some forms of secondary hypertension, such as renovascular disease, are more common at older age. Many of the causes of secondary hypertension are strongly associated with clinical findings or groups of findings that suggest a specific disorder.

Figure 3 is an algorithm on screening for secondary hypertension. Table 13 is a detailed list of clinical indications and diagnostic screening tests for secondary hypertension, and Table 14 is a list of drugs that can induce secondary hypertension.

Recommendation-Specific Supportive Text

1. The causes of secondary hypertension and recommended screening tests are provided in Table 13, and drugs that can induce secondary hypertension are provided in Table 14.

2. Diagnosis of many of these disorders requires a complex set of measurements, specialized technical expertise, and/or experience in data interpretation. Similarly, specific treatment often requires a level of technical training and experience.
Figure 3. Screening for Secondary Hypertension

New-onset or uncontrolled hypertension in adults

Conditions
- Drug-resistant/induced hypertension
- Abrupt onset of hypertension
- Onset of hypertension at <30 y
- Exacerbation of previously controlled hypertension
- Disproportionate TOD for degree of hypertension
- Accelerated/malignant hypertension
- Onset of diastolic hypertension in older adults (age ≥65 y)
- Unprovoked or excessive hypokalemia

Yes

Screen for secondary hypertension (Class I) (see Table 13)

Positive screening test

Yes

Refer to clinician with specific expertise (Class IIb)

No

Screening not indicated (No Benefit)

No

Referral not necessary (No Benefit)

Colors correspond to Class of Recommendation in Table 1.
TOD indicates target organ damage (e.g., cerebrovascular disease, hypertensive retinopathy, left ventricular hypertrophy, left ventricular dysfunction, heart failure, coronary artery disease, chronic kidney disease, albuminuria, peripheral artery disease).

5.4.1. Drugs and Other Substances With Potential to Impair BP Control

Numerous substances, including prescription medications, over-the-counter medications, herbals, and food substances, may affect BP (Table 14) (1-6). Changes in BP that occur because of drugs and other agents have been associated with the development of hypertension, worsening control in a patient who already has hypertension, or attenuation of the BP-lowering effects of antihypertensive therapy. A change in BP may also result from drug–drug or drug–food interactions (2, 4). In the clinical assessment of hypertension, a careful history should be taken with regard to substances that may impair BP control, with close attention paid to not only prescription medications, but also over-the-counter substances, illicit drugs, and herbal products. When feasible, drugs associated with increased BP should be reduced or discontinued, and alternative agents should be used.

</tbody>
</table>

Synopsis

Primary aldosteronism is defined as a group of disorders in which aldosterone production is inappropriately high for sodium status, is relatively autonomous of the major regulators of secretion (angiotensin II and potassium), and cannot be suppressed with sodium loading (2, 3). The increased production of aldosterone induces hypertension; cardiovascular and kidney damage; sodium retention; suppressed plasma renin activity; and increased potassium excretion, which, if prolonged and severe, may cause hypokalemia. However, hypokalemia is absent in the majority of cases and has a low negative predictive value for the diagnosis of primary aldosteronism (4). In about 50% of the patients, primary aldosteronism is due to increased unilateral aldosterone production (usually aldosterone-producing adenoma or, rarely, unilateral adrenal hyperplasia); in the remaining 50%, primary aldosteronism is due to bilateral adrenal hyperplasia (idiopathic hyperaldosteronism) (2, 3).

Recommendation-Specific Supportive Text

1. Primary aldosteronism is one of the most frequent disorders (occurring in 5% to 10% of patients with hypertension and 20% of patients with resistant hypertension) that causes secondary hypertension (5, 6). The toxic tissue effects of aldosterone induce greater target organ damage in primary aldosteronism than in primary hypertension. Patients with primary aldosteronism have a 3.7-fold increase in HF, a 4.2-fold increase in stroke, a 6.5-fold increase in MI, a 12.1-fold increase in atrial fibrillation (AF), increased left ventricular
hypertrophy (LVH) and diastolic dysfunction, increased stiffness of large arteries, widespread tissue fibrosis, increased remodeling of resistance vessels, and increased kidney damage as compared with patients with primary hypertension matched for BP level (6-8). Because the deleterious effects of aldosterone overproduction are often reversible with unilateral laparoscopic adrenalectomy or treatment with mineralocorticoid receptor antagonists (i.e., spironolactone or eplerenone), screening of patients with hypertension at increased risk of primary aldosteronism is beneficial (2, 3). These include hypertensive patients with adrenal “incidentaloma,” an incidentally discovered adrenal lesion on a computed tomography or magnetic resonance imaging (MRI) scan performed for other purposes. Patients with hypertension and a history of early onset hypertension and/or cerebrovascular accident at a young age may have primary aldosteronism due to glucocorticoid-remediable aldosteronism (familial hyperaldosteronism type-1) and therefore warrant screening (2, 3).

2. The aldosterone:renin activity ratio is currently the most accurate and reliable means of screening for primary aldosteronism (1). The most commonly used cutoff value is 30 when plasma aldosterone concentration is reported in nanograms per deciliter (ng/dL) and plasma renin activity in nanograms per milliliter per hour (ng/mL/h) (3). Because the aldosterone:renin activity ratio can be influenced by the presence of very low renin levels, the plasma aldosterone concentration should be at least 10 ng/dL to interpret the test as positive (3). Patients should have unrestricted salt intake, serum potassium in the normal range, and mineralocorticoid receptor antagonists (e.g., spironolactone or eplerenone) withdrawn for at least 4 weeks before testing (2, 3).

3. The diagnosis of primary aldosteronism generally requires a confirmatory test (intravenous saline suppression test or oral salt-loading test) (2, 3). If the diagnosis of primary aldosteronism is confirmed (and the patient agrees that surgery would be desirable), the patient is referred for an adrenal venous sampling procedure to determine whether the increased aldosterone production is unilateral or bilateral in origin. If unilateral aldosterone production is documented on adrenal venous sampling, the patient is referred for unilateral laparoscopic adrenalectomy, which improves BP in virtually 100% of patients and results in a complete cure of hypertension in about 50% (2, 3). If the patient has bilaterally increased aldosterone secretion on adrenal venous sampling or has a unilateral source of excess aldosterone production but cannot undergo surgery, the patient is treated with spironolactone or eplerenone as agent of choice (2, 3). Both adrenalectomy and medical therapy are effective in lowering BP and reversing LVH. Treating primary aldosteronism, either by mineralocorticoid receptor antagonists or unilateral adrenalectomy (if indicated), resolves hypokalemia, lowers BP, reduces the number of antihypertensive medications required, and improves parameters of impaired cardiac and kidney function (9, 10).

5.4.3. Renal Artery Stenosis

<table>
<thead>
<tr>
<th>COR</th>
<th>LOE</th>
<th>Recommendations</th>
</tr>
</thead>
<tbody>
<tr>
<td>I</td>
<td>A</td>
<td>1. Medical therapy is recommended for adults with atherosclerotic renal artery stenosis (1, 2).</td>
</tr>
<tr>
<td>IIb</td>
<td>C-EO</td>
<td>2. In adults with renal artery stenosis for whom medical management has failed (refractory hypertension, worsening renal function, and/or intractable HF) and those with nonatherosclerotic disease, including fibromuscular dysplasia, it may be reasonable to refer the patient for consideration of revascularization (percutaneous renal artery angioplasty and/or stent placement).</td>
</tr>
</tbody>
</table>

Synopsis
Renal artery stenosis refers to a narrowing of the renal artery that can result in a restriction of blood flow. Atherosclerotic disease (90%) is by far the most common cause of renal artery stenosis, whereas nonatherosclerotic disease (of which fibromuscular dysplasia is the most common) is much less prevalent and tends to occur in younger, healthier patients (3). Renal artery stenosis is a common form of secondary hypertension. Relieving ischemia and the ensuing postischemic release of renin by surgical renal artery reconstruction is an invasive strategy with a postoperative mortality as high as 13% (4). With the advent of endovascular procedures to restore blood flow, several trials were designed to test the efficacy of these procedures against medical therapy, but they suggested no benefit over medical therapy alone (1, 2).

Recommendation-Specific Supportive Text

1. Atherosclerotic disease in the renal arteries represents systemic disease and higher risk of both renal failure and cardiovascular morbidity and mortality. No RCT to date has demonstrated a clinical advantage of renal artery revascularization (with either angioplasty or stenting) over medical therapy (2). On the basis of the CORAL (Cardiovascular Outcomes in Renal Atherosclerotic Lesions) trial, the recommended medical approach encompasses optimal management of hypertension with an antihypertensive regimen that includes a renin-angiotensin system (RAS) blocker, in addition to low-density lipoprotein cholesterol reduction with a high-intensity statin, smoking cessation, hemoglobin A1c reduction in patients with DM, and antiplatelet therapy (1).

2. Revascularization may be considered for those who do not respond to medical therapy and for those who have nonatherosclerotic disease (e.g., Takayasu arteritis in Asian populations, fibromuscular dysplasia in other populations). Fibromuscular dysplasia occurs over the lifespan of women (mean: 53 years of age) with almost equal frequency in the renal and carotid circulations (3). Percutaneous transluminal angioplasty alone (without stenting) can improve BP control and even normalize BP, especially in patients with recent onset of hypertension or resistant hypertension (5).

5.4.4. Obstructive Sleep Apnea

<table>
<thead>
<tr>
<th>COR</th>
<th>LOE</th>
<th>Recommendations</th>
</tr>
</thead>
<tbody>
<tr>
<td>IIb</td>
<td>B-R</td>
<td>1. In adults with hypertension and obstructive sleep apnea, the effectiveness of continuous positive airway pressure (CPAP) to reduce BP is not well established (1-5).</td>
</tr>
</tbody>
</table>

Synopsis

Obstructive sleep apnea is a common chronic condition characterized by recurrent collapse of upper airways during sleep, inducing intermittent episodes of apnea/hypopnea, hypoxemia, and sleep disruption (6). Obstructive sleep apnea is a risk factor for several CVDs, including hypertension, coronary and cerebrovascular diseases, HF, and AF (6-9). Observational studies have shown that the presence of obstructive sleep apnea is associated with increased risk of incident hypertension (10, 11). Obstructive sleep apnea is highly prevalent in adults with resistant hypertension (≥80%) (12, 13), and it has been hypothesized that treatment with CPAP may have more pronounced effects on BP reduction in resistant hypertension (6).

Recommendation-Specific Supportive Text

1. CPAP is an efficacious treatment for improving obstructive sleep apnea. However, studies of the effects of CPAP on BP have demonstrated only small effects on BP (e.g., 2– to 3-mm Hg reductions), with results dependent on patient compliance with CPAP use, severity of obstructive sleep apnea, and presence of daytime sleepiness in study participants (1-5). Although many RCTs have been reported that address the effects of CPAP on BP in obstructive sleep apnea, most of the patients studied did not have documented hypertension, and the studies were too small and the follow-up period too short to allow for adequate evaluation. In addition, a well-designed RCT demonstrated that CPAP plus usual care, compared with usual care alone, did not prevent cardiovascular events in patients with moderate–severe obstructive sleep apnea and established CVD (14).

References

6. Nonpharmacological Interventions

Correcting the dietary aberrations, physical inactivity, and excessive consumption of alcohol that cause high BP is a fundamentally important approach to prevention and management of high BP, either on their own or in combination with pharmacological therapy. Prevention of hypertension and treatment of established hypertension are complementary approaches to reducing CVD risk in the population, but prevention of hypertension provides the optimal means of reducing risk and avoiding the harmful consequences of hypertension (1-3). Nonpharmacological therapy alone is especially useful for prevention of hypertension, including in adults with elevated BP, and for management of high BP in adults with milder forms of hypertension (4, 5).

References

6.1. Strategies

Nonpharmacological interventions can be accomplished by means of behavioral strategies aimed at lifestyle change, prescription of dietary supplements, or implementation of kitchen-based interventions that directly modify elements of the diet. At a societal level, policy changes can enhance the availability of healthy foods and facilitate physical activity. The goal can be to modestly reduce BP in the general population or to
undertake more intensive targeted lowering of BP in adults with hypertension or at high risk of developing hypertension (1). The intent of the general population approach is to achieve a small downward shift in the general population distribution of BP, which would be expected to result in substantial health benefits (2). The targeted approach focuses on BP reduction in adults at greatest risk of developing BP-related CVD, including individuals with hypertension, as well as those at increased risk of developing hypertension, especially blacks and adults who are overweight, consume excessive amounts of dietary sodium, have a high intake of alcohol, or are physically inactive. The targeted approach tends to be intensive, with a more ambitious goal for BP reduction. Both approaches are complementary and mutually reinforcing, and modeling studies suggest they are likely to provide similar public health benefit (3, 4). However, as the precision of risk prediction tools increases, targeted prevention strategies that focus on high-risk individuals seem to become more efficient than population-based strategies (5).

<tr>
<td>I</td>
<td>A</td>
<td>6. Adult men and women with elevated BP or hypertension who currently consume alcohol should be advised to drink no more than 2 and 1 standard drinks* per day, respectively (23-28).</td>
</tr>
</tbody>
</table>

*In the United States, 1 “standard” drink contains roughly 14 g of pure alcohol, which is typically found in 12 oz of regular beer (usually about 5% alcohol), 5 oz of wine (usually about 12% alcohol), and 1.5 oz of distilled spirits (usually about 40% alcohol) (29).
Nonpharmacological interventions are effective in lowering BP, with the most important interventions being weight loss (1), the DASH (Dietary Approaches to Stop Hypertension) diet (5-7, 30), sodium reduction (8-11), potassium supplementation (13, 17), increased physical activity (18-20, 22, 31), and a reduction in alcohol consumption (23, 24). Various other nonpharmacological interventions have been reported to lower BP, but the extent and/or quality of the supporting clinical trial experience is less persuasive. Such interventions include consumption of probiotics (32, 33, 34); increased intake of protein (35-37), fiber (38, 39), flaxseed (40), or fish oil (41); supplementation with calcium (42, 43) or magnesium (44, 45); and use of dietary patterns other than the DASH diet, including low-carbohydrate and vegetarian diets (5, 7, 46-49), (18-20, 22, 23, 31, 50). Stress reduction is intuitively attractive but insufficiently proved (51), as are several other interventions, including consumption of garlic (52), dark chocolate (53, 54), tea (55), or coffee (56). Behavioral therapies, including guided breathing, yoga, transcendental meditation, and biofeedback, lack strong evidence for their long-term BP-lowering effect (51, 57-61). The best proven nonpharmacological measures to prevent and treat hypertension are summarized in Table 15 (62).

The nonpharmacological interventions presented in Table 15 may be sufficient to prevent hypertension and meet goal BP in managing patients with stage 1 hypertension, and they are an integral part of the management of persons with stage 2 hypertension. To a lesser extent, the Mediterranean diet (49, 63) (which incorporates the basics of healthy eating but emphasizes consumption of legumes and monounsaturated fat, avoidance of red meats, and moderate intake of wine) has been effective in reducing BP, as well as improving lipid profile.

Table 15 is a summary of best proven nonpharmacological interventions for prevention and treatment of hypertension.

Recommendation-Specific Supportive Text

1. Weight loss is a core recommendation and should be achieved through a combination of reduced calorie intake and increased physical activity (1). The BP-lowering effect of weight loss in patients with elevated BP is consistent with the corresponding effect in patients with established hypertension, with an apparent dose-response relationship of about 1 mm Hg per kilogram of weight loss. Achievement and maintenance of weight loss through behavior change are challenging (64-66) but feasible over prolonged periods of follow-up (64). For those who do not meet their weight loss goals with nonpharmacological interventions, pharmacotherapy or minimally invasive and bariatric surgical procedures can be considered (67, 68). Surgical procedures tend to be more effective but are usually reserved for those with more severe and intractable obesity because of the frequency of complications. (69)

2. The DASH eating plan is the diet best demonstrated to be effective for lowering BP. Because the DASH diet is high in fruits, vegetables, and low-fat dairy products, it provides a means to enhance intake of potassium, calcium, magnesium, and fiber. In hypertensive and nonhypertensive adults, the DASH diet has produced overall reductions in SBP of approximately 11 mm Hg and 3 mm Hg, respectively (7), and the diet was especially effective in blacks (70). When combined with weight loss (6) or a reduction in sodium intake (5, 30), the effect size was substantially increased. Most of the clinical trial experience comes from short-term feeding studies (7), but lifestyle change with the DASH diet has been successful in at least 2 trials that used a behavioral intervention over a 4-month (30) or 6-month (6) period of follow-up. Websites and books provide advice on implementation of the DASH diet. (13, 71-74) Counseling by a knowledgeable nutritionist can be helpful. Several other diets, including diets that are low in calories from carbohydrates (46), high-protein diets (75), vegetarian diets (48), and a Mediterranean dietary pattern (49, 63), have been shown to lower BP.

3. Sodium reduction interventions prevent hypertension and lower BP in adults with hypertension, especially in those with higher levels of BP, blacks, older persons, and others who are particularly susceptible to the
effects of sodium on BP (8-11). Sodium reduction interventions may prevent CVD (76, 77). Lifestyle change (behavioral) interventions usually reduce sodium intake by about 25% (approximately 1,000 mg per day) and result in an average of about a 2–mm Hg to 3–mm Hg reduction in SBP in nonhypertensive individuals, though the reduction can be more than double this in more susceptible individuals, those with hypertension, and those concurrently on the DASH diet (5) or following a weight loss intervention (12). Sodium reduction in adults with hypertension who are already being treated with BP-lowering medications further reduces SBP by about 3 mm Hg and can facilitate discontinuation of medication, although this requires maintenance of the lifestyle change and warrants careful monitoring (12). When combined with weight loss, the reduction in BP is almost doubled. A reduction in sodium intake may also lower SBP significantly in individuals with resistant hypertension who are taking multiple antihypertensive medications (78) (see Section 11.1). Reduced dietary sodium has been reported to augment the BP-lowering effects of RAS blocker therapy (79). Maintenance of the lifestyle changes necessary to reduce sodium intake is challenging (2-4, 12), but even a small decrement in sodium consumption is likely to be safe (2, 4, 9, 12, 80) and beneficial (8, 81), especially in those whose BP is salt sensitive (82). In the United States, most dietary sodium comes from additions during food processing or during commercial food preparation at sit-down and fast-food restaurants (83, 84). Person-specific and policy approaches can be used to reduce dietary sodium intake (85, 86). Individuals can take action to reduce their dietary intake of sodium by choice of fresh foods, use of food labels to choose foods that are lower in sodium content, choice of foods with a “no added sodium” label, judicious use of condiments and sodium-infused foods, use of spices and low-sodium flavorings, careful ordering when eating out, control of food portion size, and avoiding or minimizing use of salt at the table. Dietary counseling by a nutritionist with expertise in behavior modification can be helpful. A reduction in the amount of sodium added during food processing, as well as fast food and restaurant food preparation, has the potential to substantially reduce sodium intake without the need for a conscious change in lifestyle (81, 85, 87).

4. Dietary potassium is inversely related to BP and hypertension in migrant studies (88), cross-sectional reports (89-91), and prospective cohort studies (92). Likewise, dietary potassium (93-96) and a high intake of fruits and vegetables are associated with a lower incidence of stroke (97). Potassium interventions have been effective in lowering BP (13, 14, 16, 81), especially in adult patients consuming an excess of sodium (13, 74, 98) and in blacks (13). The typical BP-lowering effect of a 60-mmol (1380-mg) administration of potassium chloride has been about 2 mm Hg and 4 to 5 mm Hg in adults with normotension and hypertension, respectively, although the response is up to twice as much in persons consuming a high-sodium diet. A reduction in the sodium/potassium index may be more important than the corresponding changes in either electrolyte alone (99). Some but not all studies suggest that the intervention effect may be restricted to adult patients with a low (1500-mg to 2000-mg) daily intake of potassium (92, 100). Most of the intervention experience comes from trials of relatively short duration (median of 5 to 6 weeks) (13, 14), but the BP-lowering effect of potassium in adult patients consuming a high-sodium diet has been reproduced after an interval of 4.4 years (98). In most trials, potassium supplementation was achieved by administration of potassium chloride pills, but the BP response pattern was similar when dietary modification was used (13). Because potassium-rich diets tend to be heart healthy, they are preferred over use of pills for potassium supplementation. The 2015 Dietary Guidelines for Americans (101) encourage a diet rich in potassium and identify the adequate intake level for adult patients as 4700 mg/day (102). The World Health Organization recommends a potassium intake of at least 90 mmol (3510 mg) per day from food for adult patients (15). Good sources of dietary potassium include fruits and vegetables, as well as low-fat dairy products, selected fish and meats, nuts, and soy products. Four to five servings of fruits and vegetables will usually provide 1500 to >3000 mg of potassium. This can be achieved by a diet, such as the DASH diet, that is high in potassium content (6).

5. A BP-lowering effect of increased physical activity has been repeatedly demonstrated in clinical trials, especially during dynamic aerobic exercise (18, 20, 22), but also during dynamic resistance training (18, 21) and static isometric exercise (18, 19, 31). The average reductions in SBP with aerobic exercise are
approximately 2 to 4 mm Hg and 5 to 8 mm Hg in adult patients with normotension and hypertension, respectively (18). Most trials have been of relatively short duration, but increased physical activity has been an intrinsic component of longer-term weight reduction interventions used to reduce BP and prevent hypertension (3, 4, 12). BP-lowering effects have been reported with lower- and higher-intensity exercise and with continuous and interval exercise training (18, 103). Meta-analyses suggest isometric exercise results in substantial lowering of BP (18, 19, 31).

6. In observational studies, there is a strong, predictable direct relationship between alcohol consumption and BP, especially above an intake of 3 standard drinks per day (approximately 36 ounces of regular beer, 15 ounces of wine, or 4.5 ounces of distilled spirits) (29, 104, 105). Meta-analyses of RCTs that have studied the effect of reduced alcohol consumption on BP in adults have identified a significant reduction in SBP and DBP (23, 24). The benefit has seemed to be consistent across trials, but confined to those consuming ≥3 drinks/day, as well as dose dependent, with those consuming ≥6 drinks/day at baseline reducing their alcohol intake by about 50% and experiencing an average reduction in SBP/DBP of approximately 5.5/4.0 mm Hg (23, 24). Only limited information is available on the effect of alcohol reduction on BP in blacks (23, 106). In contrast to its effect on BP, alcohol seems to have a beneficial effect on several biomarkers for CVD risk, including high-density lipoprotein cholesterol (107, 108). Observational studies have shown a relatively consistent finding of an inverse relationship between alcohol intake and CHD (109, 110), within a moderate range (approximately 12–14 and ≤9 standard drinks/week for men and women, respectively). On balance, it seems reasonable for those who are consuming moderate quantities of alcohol (≤2 drinks/day) to continue their moderate consumption of alcohol.

7. Patient Evaluation

The patient evaluation is designed to identify target organ damage and possible secondary causes of hypertension and to assist in planning an effective treatment regimen. Historical features are relevant to the evaluation of the patient (Table 16). The pattern of BP measurements and changes over time may differentiate primary from secondary causes of hypertension. A rise in BP associated with weight gain, lifestyle factors (such as a job change requiring travel and meals away from home), reduced frequency or intensity of physical activity, or advancing age in a patient with a strong family history of hypertension would suggest the diagnosis of primary hypertension. An evaluation of the patient’s dietary habits, physical activity, alcohol consumption, and tobacco use should be performed, with recommendation of the nonpharmacological interventions detailed in Section 6.2 where appropriate. The history should also include inquiry into possible occurrence of symptoms to indicate a secondary cause (Tables 13 and 16). The patient’s treatment goals and risk tolerance should also be elicited. This is especially true for older persons, for whom an assessment of multiple chronic conditions, frailty, and prognosis should be performed, including consideration of the time required to see benefit from intervention, which may not be realized for some individuals.
The physical examination should include accurate measurement of BP (Table 8). Automated oscillometric devices provide an opportunity to obtain repeated measurements without a provider present, thereby minimizing the potential for a white coat effect. Change in BP from seated to standing position should be measured to detect orthostatic hypotension (a decline >20 mm Hg in SBP or >10 mm Hg in DBP after 1 minute is abnormal). For adults ≤30 years of age with elevated brachial BP, a thigh BP measurement is indicated; if the thigh measurement is lower than arm pressures, a diagnosis of coarctation of the aorta should be considered. The physical examination should include assessment of hypertension-related target organ damage. Attention should be paid to physical features that suggest secondary hypertension (Table 13).

7.1. Laboratory Tests and Other Diagnostic Procedures

Laboratory measurements should be obtained for all patients with a new diagnosis of hypertension to facilitate CVD risk factor profiling, establish a baseline for medication use, and screen for secondary causes of hypertension (Table 17). Optional tests may provide information on target organ damage. Monitoring of serum sodium and potassium levels is helpful during diuretic or RAS blocker titration, as are serum creatinine and urinary albumin as markers of CKD progression (1). Measurement of thyroid-stimulating hormone is a simple test to easily detect hyperthyroidism and hyperthyroidism, 2 remediable causes of hypertension. A decision to conduct additional laboratory testing would be appropriate in the context of increased hypertension severity, poor response to standard treatment approaches, a disproportionate severity of target organ damage for the level of BP, or historical or clinical clues that support a secondary cause.

7.2. Cardiovascular Target Organ Damage

Pulse-wave velocity, carotid intima-media thickness, and coronary artery calcium score provide noninvasive estimates of vascular target organ injury and atherosclerosis (1). High BP readings, especially when obtained several years before a noninvasive measurement, are associated with an increase in subclinical CVD risk (2-4). Although carotid intima-media thickness values and coronary artery calcium scores are associated with cardiovascular events, inadequate or absent information on the effect of improvement in these markers on cardiovascular events prevents their routine use as surrogate markers in the treatment of hypertension.

LVH is a secondary manifestation of hypertension and independently predicts future CVD events. LVH is commonly measured by electrocardiography, echocardiography, or MRI (5, 6). Left ventricular (LV) mass is associated with body size (particularly lean body mass), tobacco use, heart rate (inverse), and long-standing DM (7-9). BP lowering leads to a reduction in LV mass. In TOMHS (Treatment of Mild Hypertension Study), the long-acting diuretic chlorthalidone was slightly more effective in reducing LVH than were a calcium channel blocker (CCB) (amlodipine), ACE inhibitor (enalapril), alpha-receptor blocker (doxazosin), or beta-receptor blocker (acebutolol) (10). Beta blockers are inferior to angiotensin receptor blockers (ARBs), angiotensin-converting enzyme (ACE) inhibitors, and CCBs in reducing LVH (11).

Hypertension adversely impacts other echocardiographic markers of cardiac structure and function, including left atrial size (both diameter and area; left atrial size is also a precursor of AF); diastolic function (many parameters; a precursor of HF with preserved ejection fraction [HFpEF]); cardiac structure; and subclinical markers of LV systolic function, such as myocardial strain assessment with echocardiography and MRI.

Assessment of LVH by means of echocardiography or MRI is not universally recommended during evaluation and management of hypertension in adults because there are limited data on the cost and value of these measures for CVD risk reclassification and changes in type or intensity of treatment. Assessment of LVH is most useful in adults who are young (≤18 years of age) or have evidence of secondary hypertension, chronic uncontrolled hypertension, or history of symptoms of HF. Electrocardiographic criteria for LVH correlate weakly with echocardiographic or MRI definitions of LVH and are less strongly related to CVD outcomes (12-15). Imprecision in lead placement accounts, in part, for the poor correlation of electrocardiographic measurements with direct imaging results. However, electrocardiographic LVH has been valuable in predicting CVD risk in some reports (16, 17). Electrocardiography may also be useful in the assessment of comorbidities, such as rhythm disturbances and prior MI.

LVH, as assessed by electrocardiography, echocardiography, or MRI, is an independent predictor of CVD complications (18, 19). Reduction in LVH can predict a reduction in CVD risk, independent of change in BP (20). When used in CVD risk predictor models, echocardiographic LVH has a small but significant independent effect on CVD risk in younger patients. At older ages, LVH measured by electrocardiography or MRI provides no independent contribution to prediction of CVD risk (21-23).

8. Treatment of High BP

Clinicians managing adults with high BP should focus on overall patient health, with a particular emphasis on reducing the risk of future adverse CVD outcomes. All patient risk factors need to be managed in an integrated fashion with a comprehensive set of nonpharmacological (see Section 6) and pharmacological strategies. As patient BP and risk of future CVD events increase, BP management should be intensified.

8.1. Pharmacological Treatment

8.1.1. Initiation of Pharmacological BP Treatment in the Context of Overall CVD Risk

For any specific difference in BP, the relative risk of CVD is constant across groups that differ in absolute risk of atherosclerotic CVD (1-4), albeit with some evidence of lesser relative risk but greater excess risk in older than in younger adults (5-8). Thus, there are more potentially preventable CVD events attributable to elevated BP in individuals with higher than with lower risk of CVD and in older than in younger adults. The relative risk reduction for CVD prevention with use of BP-lowering medications is fairly constant for groups that differ in CVD risk across a wide range of estimated absolute risk (9, 10) and across groups defined by sex, age, body mass index, and the presence or absence of DM, AF, and CKD (5, 11-21). As a consequence, the absolute CVD risk reduction attributable to BP lowering is greater at greater absolute levels of CVD risk (9, 10, 12, 15-19, 22, 23). Put another way, for a given magnitude of BP reduction due to antihypertensive medications, fewer individuals at high CVD risk would need to be treated to prevent a CVD event (i.e., lower number needed to treat) than those at low CVD risk.

*ACC/AHA Pooled Cohort Equations (http://tools.acc.org/ASCVD-Risk-Estimator/) (13a) to estimate 10-year risk of atherosclerotic CVD. ASCVD was defined as a first CHD death, non-fatal MI or fatal or non-fatal stroke.

Synopsis

Whereas treatment of high BP with BP-lowering medications on the basis of BP level alone is considered cost effective (14), use of a combination of absolute CVD risk and BP level to guide such treatment is more efficient and cost effective at reducing risk of CVD than is use of BP level alone (15-24). Practical approaches have been developed to translate evidence from RCTs into individual patient treatment recommendations that are based on absolute net benefit for CVD risk (25), and several national and international guidelines recommend basing use of BP-lowering medications on a combination of absolute risk of CVD and level of BP instead of relying solely on level of BP (26-31).

Attempts to use absolute risk to guide implementation of pharmacological treatment to prevent CVD have had mixed results, with many reports of improvements in provider prescribing behaviors, patient adherence, and reductions in risk (32-38), but with others showing no impact on provider behaviors (39, 40). Use of global CVD risk assessment is infrequent in routine clinical practice (41-46), which suggests that intensive efforts would be required to achieve universal implementation. The choice of specific risk calculators for estimation of risk and risk threshold has been an important source of variability, ambiguity, and controversy (47-54). In addition, implementation of a standard (worldwide) absolute CVD risk threshold for initiating use of BP-lowering medications would result in large variations in medication use at a given level of BP across countries (48, 54, 55). Future research in this area should focus on issues related to implementation of a risk-based approach to CVD prevention, including the use of BP-lowering medications. Although several CVD risk assessment tools are available, on the basis of current knowledge, we recommend use of the ACC/AHA Pooled Cohort Equations (http://tools.acc.org/ASCVD-Risk-Estimator/) to estimate 10-year risk of atherosclerotic CVD (ASCVD) to establish the BP threshold for treatment (56, 57). It should be kept in mind that the ACC/AHA Pooled Cohort Equations are validated for U.S. adults ages 45 to 79 years in the absence of concurrent statin therapy (56). For those older than age 79, the 10-year ASCVD risk is generally >10%, and thus the SBP threshold for antihypertensive drug treatment for patients >79 years old is 130 mm Hg. Two recent reviews have highlighted the importance of using predicted CVD risk together with BP to guide antihypertensive drug therapy (22, 23).

Figure 4 is an algorithm on BP thresholds and recommendations for treatment and follow-up.
Recommendation-Specific Supportive Text

1. For the purposes of secondary prevention, clinical CVD is defined as CHD, congestive HF, and stroke. Several meta-analyses of RCTs support the value of using BP-lowering medications, in addition to nonpharmacological treatment, in patients with established CVD in the absence of hypertension, defined previously by an SBP ≥140 mm Hg or a DBP ≥90 mm Hg (1, 6, 7, 9). Many RCTs of BP lowering in adults without CVD have used inclusion criteria designed to increase the level of CVD risk in the study populations to increase trial efficiency by facilitating shorter duration and a smaller sample size. As a consequence, few relatively low-risk adults with hypertension have been included in the trials. Trial results provide evidence of CVD prevention from use of BP-lowering medications in adults with an average SBP ≥130 mm Hg or an average DBP ≥80 mm Hg and clinical CVD; 5-year risk of CVD (defined as stroke, CHD, HF, or other CVD death) of approximately 6% to 7% (3, 5); an estimated 10-year CVD death rate of approximately 4.5% (4); or an annual rate of major CVD events of approximately 0.9% per year (7). In the absence of clinical CVD, these risk estimates are roughly equivalent to a 10-year risk of ASCVD exceeding 10% as per the ACC/AHA Pooled Cohort Equations (56). SPRINT (Systolic Blood Pressure Intervention Trial) provides additional support for the use of BP-lowering medications in patients without CVD at SBP levels ≥130 mm Hg; however, it is important to note that few SPRINT participants had untreated SBP between 130 mm Hg and 139 mm Hg at baseline. Furthermore, SPRINT used a Framingham 10-year risk of general CVD exceeding 15% to identify increased CVD risk (8). Although this level of risk is lower than the levels described previously, being roughly equivalent to a 6% to 7% 10-year ASCVD risk per the ACC/AHA Pooled Cohort Equations, most of the participants in SPRINT had a much higher level of CVD risk. This recommendation differs from JNC 7 in its use of CVD risk, rather than diabetes or CKD, to recognize patients, including older adults, with a SBP/DBP <140/90 mm Hg who are likely to benefit from BP lowering drug therapy in addition to nonpharmacological antihypertensive treatment. In JNC 7, the BP threshold for initiation of antihypertensive drug therapy was ≥ 140/90 mm Hg for the general adult population and ≥ 130/80 mm Hg for adults with diabetes or CKD. Since the publication of JNC 7 in 2003, we have gained additional experience with risk assessment and new data from randomized trials, observational studies and simulation analyses have demonstrated that antihypertensive drug treatment based on overall ASCVD risk assessment combined with BP levels may prevent more CVD events than treatment based on BP levels alone (15-24). According to an analysis of NHANES 2011-2014, the new definition results in only a small increase in the percentage of U.S. adults for whom antihypertensive medication is recommended in conjunction with lifestyle modification. The previously cited meta-analyses are consistent with the conclusion that lowering of BP results in benefit in higher-risk individuals, regardless of their baseline treated or untreated BP ≥130/80 mm Hg and irrespective of the specific cause of their elevated risk. These analyses indicate that the benefit of treatment outweighs the potential harm at threshold BP ≥130/80 mm Hg.

2. This recommendation is consistent with prior guidelines, such as JNC 7. In addition, for those for whom nonpharmacological therapy has been ineffective, antihypertensive drug treatment should be added in patients with an SBP ≥140 mm Hg or a DBP ≥90 mm Hg, even in adults who are at lower risk than those included in RCTs. The rationale for drug treatment in patients with an SBP ≥140 mm Hg or a DBP ≥90 mm Hg and an estimated 10-year risk of CVD <10% is based on several lines of evidence. First, the relationship of SBP with risk of CVD is known to be continuous across levels of SBP and similar across groups that differ in level of absolute risk (10). Second, the relative risk reduction attributable to BP-lowering medication therapy is consistent across the range of absolute risk observed in trials (3, 11, 58), supporting the contention that the relative risk reduction may be similar at lower levels of absolute risk. This is the case even in a meta-analysis of trials in adults without clinical CVD and an average SBP/DBP of 146/84 mm Hg (5). Finally, modeling studies support the effectiveness and cost-effectiveness of treatment of younger, lower-risk patients over the course of their life spans (12, 13). Although the numbers needed to treat with BP-lowering medications to prevent a CVD event in the short term are greater in younger, lower-risk individuals with hypertension than in older, higher-risk adults with hypertension, the estimated gains in life expectancy attributable to long-term use of...
BP-lowering medications are correspondingly greater in younger, lower-risk individuals than in older adults with a higher risk of CVD (12, 13). Indirect support is also provided by evidence from trials using BP-lowering medications to reduce the risk of developing higher levels of BP (59-61) and, in one case, to achieve a reduction in LV mass (62). In the HOPE-3 (Heart Outcomes Prevention Evaluation-3) BP Trial, there was no evidence of short-term benefit during treatment of adults (average age 66 years) with a relatively low risk of CVD (3.8% CVD event rate during 5.6 years of follow-up). However, subgroup analysis suggested benefit in those with an average SBP approximately >140 mm Hg (and a CVD risk of 6.5% during the 5.6 years of follow-up) (63). We acknowledge the importance of excluding white coat hypertension before initiating pharmacological therapy in hypertensive patients with low ASCVD risk. This may be accomplished (as described in Section 4) by HBPM or ABPM as appropriate.

Figure 4. Blood Pressure (BP) Thresholds and Recommendations for Treatment and Follow-Up

Colors correspond to Class of Recommendation in Table 1.
*Using the ACC/AHA Pooled Cohort Equations (57). Note that patients with DM or CKD are automatically placed in the high-risk category. For initiation of RAS inhibitor or diuretic therapy, assess blood tests for electrolytes and renal function 2 to 4 weeks after initiating therapy.
†Consider initiation of pharmacological therapy for stage 2 hypertension with 2 antihypertensive agents of different classes. Patients with stage 2 hypertension and BP ≥160/100 mm Hg should be promptly treated, carefully monitored, and subject to upward medication dose adjustment as necessary to control BP. Reassessment includes BP measurement, detection of orthostatic hypotension in selected patients (e.g., older or with postural symptoms), identification of white coat hypertension or a white coat effect, documentation of adherence, monitoring of the
response to therapy, reinforcement of the importance of adherence, reinforcement of the importance of treatment, and assistance with treatment to achieve BP target.

ACC indicates American College of Cardiology; AHA, American Heart Association; ASCVD, atherosclerotic cardiovascular disease; BP, blood pressure; CKD, chronic kidney disease; DM, diabetes mellitus; and RAS, renin-angiotensin system.

Synopsis

An important component of BP management in hypertensive patients is follow-up. Different periods of time for follow-up are recommended depending on the stage of hypertension, the presence or absence of target organ damage, treatment with antihypertensive medications, and the level of BP control. Recommendations for follow-up are summarized in Figure 4.

Recommendation-Specific Supportive Text

1. Nonpharmacological therapy (see Section 6.2) is the preferred therapy for adults with elevated BP and an appropriate first-line therapy for adults with stage 1 hypertension who have an estimated 10-year ASCVD risk of <10%. Adherence to and impact of nonpharmacological therapy should be assessed within 3 to 6 months.

2. Nonpharmacological therapy can help reduce BP in patients with stage 1 hypertension with an estimated 10-year ASCVD risk of ≥10% and should be used in addition to pharmacological therapy as first-line therapy in such patients (see Section 6.2).

3. Prompt evaluation and treatment of patients with stage 2 hypertension with a combination of drug and nonpharmacological therapy are important because of the elevated risk of CVD events in this subgroup, especially those with multiple ASCVD risk factors or target organ damage (1, 2).

4. Prompt management of very high BP is important to reduce the risk of target organ damage (see Section 11.2). The rapidity of the treatment needed is dependent on the patient’s clinical presentation (presence of new or worsening target organ damage) and presence or absence of CVD complications, but treatment should be initiated within at least 1 week.

5. Given that the lifetime risk of hypertension exceeds 80% in U.S. adults (3), it is likely that individuals with a normal BP will develop elevated BP in the future. BP may change over time because of changes in BP-related lifestyle factors, such as degree of sedentary lifestyle, dietary sodium intake, body weight, and alcohol intake.
Less commonly, secondary causes of hypertension can occur over time and lead to an increase in BP. Periodic BP screening can identify individuals who develop elevated BP over time. More frequent BP screening may be particularly important for individuals with elevated ASCVD risk.

<td>III: Harm</td>
<td>A</td>
<td>1. Simultaneous use of an ACE inhibitor, ARB, and/or renin inhibitor is potentially harmful and is not recommended to treat adults with hypertension (1-3).</td>
</tr>
</tbody>
</table>

**Synopsis**

Pharmacological agents, in addition to lifestyle modification (see Section 6.2), provide the primary basis for treatment of high BP. A large number of clinical trials have demonstrated that antihypertensive pharmacotherapy not only lowers BP but reduces the risk of CVD, cerebrovascular events, and death (4-7).

Numerous classes of antihypertensive agents are available to treat high BP (Table 18). Agents that have been shown to reduce clinical events should be used preferentially. Therefore, the primary agents used in the treatment of hypertension include thiazide diuretics, ACE inhibitors, ARBs, and CCBs (8-11) (see Section 8.1.6). Although many other drugs and drug classes are available, either confirmation that these agents decrease clinical outcomes to an extent similar to that of the primary agents is lacking, or safety and tolerability may relegate their role to use as secondary agents. In particular, there is inadequate evidence to support the initial use of beta blockers for hypertension in the absence of specific cardiovascular comorbidities (see Section 9).

When the initial drug treatment of high BP is being considered, several different strategies may be contemplated. Many patients can be started on a single agent, but consideration should be given to starting with 2 drugs of different classes for those with stage 2 hypertension (see Section 8.1.6.1). In addition, other patient-specific factors, such as age, concurrent medications, drug adherence, drug interactions, the overall treatment regimen, out-of-pocket costs, and comorbidities, should be considered. From a societal perspective, total costs must be taken into account. Shared decision making, with the patient influenced by clinician judgment, should drive the ultimate choice of antihypertensive agent(s).

Many patients started on a single agent will subsequently require ≥2 drugs from different pharmacological classes to reach their BP goals (12, 13, 14). Knowledge of the pharmacological mechanisms of action of each agent is important. Drug regimens with complementary activity, where a second antihypertensive agent is used to block compensatory responses to the initial agent or affect a different pressor mechanism, can result in additive lowering of BP. For example, thiazide diuretics may stimulate the renin-angiotensin-aldosterone system. By adding an ACE inhibitor or ARB to the thiazide, an additive BP-lowering effect may be obtained (13). Use of combination therapy may also improve adherence. Several 2- and 3-fixed-dose drug combinations of antihypertensive drug therapy are available, with complementary
mechanisms of action among the components (Online Data Supplement D). However, it should be noted that many triple-dose combinations may contain a lower-than-optimal dose of thiazide diuretic.

Table 18 is a summary of oral antihypertensive drugs.

Recommendation-Specific Supportive Text

1. Drug combinations that have similar mechanisms of action or clinical effects should be avoided. For example, 2 drugs from the same class should not be administered together (e.g., 2 different beta blockers, ACE inhibitors, or nondihydropyridine CCBs). Likewise, 2 drugs from classes that target the same BP control system are less effective and potentially harmful when used together (e.g., ACE inhibitors, ARBs). Exceptions to this rule include concomitant use of a thiazide diuretic, K-sparing diuretic, and/or loop diuretic in various combinations. Also, dihydropyridine and nondihydropyridine CCBs can be combined. High-quality RCT data demonstrate that simultaneous administration of RAS blockers (i.e., ACE inhibitor with ARB; ACE inhibitor or ARB with renin inhibitor aliskiren) increases cardiovascular and renal risk (1-3).

### Diuretics—aldosterone antagonists

- **Eplerenone** 50–100 mg/day, 12 doses/day
  - Avoid in patients with significant CKD (e.g., GFR < 45 mL/min).
  - These are preferred agents in primary aldosteronism and resistant hypertension.
  - Spironolactone is associated with greater risk of gynecomastia and impotence as compared with eplerenone.
  - This is common add-on therapy in resistant hypertension.
  - Avoid use with K+ supplements, other K+-sparing diuretics, or significant renal dysfunction.
  - Eplerenone often requires twice-daily dosing for adequate BP lowering.

- **Spironolactone** 25–100 mg/day
  - Beta blockers are not recommended as first-line agents unless the patient has IHD or HF.
  - These are preferred in patients with bronchospastic airway disease requiring a beta blocker.
  - Bisoprolol and metoprolol succinate are preferred in patients with HF.
  - Avoid abrupt cessation.

Synopsis

Refer to the “Systematic Review for the 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults” for the complete systematic evidence review for additional data and analyses (10). Several trials have tested whether more intensive BP control improves major CVD outcomes. Meta-analyses and systematic reviews of these trials provide strong support for the more intensive approach, but the data are less clear in identification of a specific optimal BP target (1-5, 7, 11-13). Recent trials that address optimal BP targets include SPRINT and ACCORD (Action to Control Cardiovascular Risk in Diabetes), with targets for more intensive (SBP <120 mm Hg) and standard (SBP <140 mm Hg) treatment (14, 15), and SPS-3, with a more intensive target of <130/80 mm Hg (16). These trials yielded mixed results in achieving their primary endpoints. SPRINT was stopped early, after a median follow-up of 3.26 years, when more intensive treatment resulted in a significant reduction in the primary outcome (a CVD composite) and in all-cause mortality rate. In ACCORD, more intensive BP treatment failed to demonstrate a significant reduction in the primary outcome (a CVD composite). However, the incidence of stroke, a component of the primary outcome, was significantly reduced. The standard glycemia subgroup did show significant benefit in ACCORD, and a meta-analysis of the only 2 trials (ACCORD and SPRINT) testing an SBP goal of <120 mm Hg showed significant reduction in CVD events (17). SPS-3 failed to demonstrate benefit for the primary endpoint of recurrent stroke (p=0.08) but found a significant reduction in a subgroup with hemorrhagic stroke. Pooling of the experience from 19 trials (excluding SPRINT) that randomly assigned participants to different BP treatment targets identified a significant reduction in CVD events, MI, and stroke in those assigned to a lower (average achieved SBP/DBP was 133/76 mm Hg) versus a higher BP treatment target (2). Similar patterns of benefit were reported in 3 other meta-analyses of trials in which participants were randomly assigned to different BP targets (3-5) and in larger meta-analyses that additionally included trials that compared different intensities of treatment (12). Data from the most recent meta-analysis (42 trials and 144,220 patients) (5) demonstrate a linear association between mean achieved SBP and risk of CVD mortality with the lowest risk at 120 to 124 mm Hg. The totality of the available information provides evidence that a lower BP target is generally better than a higher BP target and that some patients will benefit from an SBP treatment goal <120 mm Hg, especially those at high risk of CVD (15). The specific inclusion and exclusion criteria of any RCT may limit extrapolation to a more general population with hypertension. In addition, all of the relevant trials have been efficacy studies in which BP measurements were more consistent with guideline recommendations than is common in clinical practice, resulting in lower...
absolute values for SBP. For both of these reasons, the SBP target recommended during BP lowering (<130 mm Hg) is higher than that which was used in SPRINT.

Recommendation-Specific Supportive Text

1. Meta-analysis and systematic review of trials that compare more intensive BP reduction to standard BP reduction report that more intense BP lowering significantly reduces the risk of stroke, coronary events, major cardiovascular events, and cardiovascular mortality (1). In a stratified analysis of these data, achieving an additional 10–mm Hg reduction in SBP reduced CVD risk when compared with an average SBP of 158/82 to 143/76 mm Hg, 144/85 to 137/81 mm Hg, and 134/79 to 125/76 mm Hg. Patients with DM and CKD were included in the analysis (1, 2, 11-13, 18). (Specific management details are in Section 9.3 for CKD and Section 9.6 for DM.)

2. The treatment of patients with hypertension without elevated risk has been systematically understudied because lower-risk groups would require prolonged follow-up to have a sufficient number of clinical events to provide useful information. Although there is clinical trial evidence that both drug and nondrug therapy will interrupt the progressive course of hypertension (6), there is no trial evidence that this treatment decreases CVD morbidity and mortality. The clinical trial evidence is strongest for a target BP of 140/90 mm Hg in this population. However, observational studies suggest that these individuals often have a high lifetime risk and would benefit from BP control earlier in life (19, 20).

Synopsis

The overwhelming majority of persons with BP sufficiently elevated to warrant pharmacological therapy may be best treated initially with 2 agents (see Section 8.1.6.1). When initiation of pharmacological therapy with a single medication is appropriate, primary consideration should be given to comorbid conditions (e.g., HF, CKD) for which specific classes of BP-lowering medication are indicated (see Section 9) (1, 3). In the largest head-to-head comparison of first-step drug therapy for hypertension (4, 5), the thiazide-type diuretic chlorthalidone was superior to the CCB amlodipine and the ACE inhibitor lisinopril in preventing HF, a BP-related outcome of increasing importance in the growing population of older persons with hypertension (6-9). Additionally, ACE inhibitors were less effective than thiazide diuretics and CCBs in lowering BP and in prevention of stroke. For black patients, ACE inhibitors were also notably less effective than CCBs in preventing HF (5, 10) and in the prevention of stroke (11, 12) (see Section 10.1). ARBs may be better tolerated than ACE inhibitors in black patients, with less cough and angioedema, but according to the limited available experience they offer no proven advantage over ACE inhibitors in preventing stroke or CVD in this population, making thiazide diuretics (especially chlorthalidone) or CCBs the best initial choice for single-drug therapy. For stroke, in the general population, beta blockers were less effective than CCBs (36% lower risk) and thiazide diuretics (30% lower risk). CCBs have been shown to be as effective as diuretics for reducing all CVD events other than HF, and CCBs are a good alternative choice for initial therapy when thiazide diuretics are not tolerated. Alpha blockers are not used as first-line therapy for hypertension because they are less effective for prevention of CVD than other first-step agents, such as thiazide diuretics (4, 13).

Recommendation-Specific Supportive Text

1. The overall goal of treatment should be reduction in BP, in the context of underlying CVD risk. Five drug classes have been shown, in high-quality RCTs, to prevent CVD as compared with placebo (diuretics, ACE inhibitors, ARBs, CCBs, and beta blockers) (14, 15). In head-to-head comparisons of first-step therapy, different drug classes have been reported to provide somewhat divergent capacity to prevent specific CVD events. Interpretation of meta-analyses comparing agents from different drug classes is challenging because the
relevant RCTs were conducted in different time periods, during which concurrent antihypertensive therapy was less or more common, and the efficacy of agents from certain drug classes may have changed. In recognition of this, some (2) but not all (14, 15) meta-analyses, as well as the largest individual RCT that compared first-step agents (4), have suggested that diuretics, especially the long-acting thiazide-type agent chlorthalidone, may provide an optimal choice for first-step drug therapy of hypertension. In contrast, some meta-analyses have suggested that beta blockers may be less effective, especially for stroke prevention in older adults, but interpretation is hampered by inclusion of RCTs that used beta blockers that are now considered to be inferior for prevention of CVD (16, 17). In a systematic review and network meta-analysis conducted for the present guideline, beta blockers were significantly less effective than diuretics for prevention of stroke and cardiovascular events (1). Diuretics were also significantly better than CCBs for prevention of HF. There were some other nonsignificant differences between diuretics, ACE inhibitors, ARBs, and CCBs, but the general pattern was for similarity in effect. As indicated in Section 8.1.6.1, most adults with hypertension require more than one drug to control their BP. As recommended in Section 10.1, for black adults with hypertension (without HF or CKD), initial antihypertensive treatment should include a thiazide diuretic or CCB.

*Fixed-dose combination antihypertensive medications are listed in Online Data Supplement D.

Synopsis

Systematic review of the evidence comparing the initiation of antihypertensive treatment with monotherapy and sequential (stepped-care) titration of additional agents versus initiation of treatment with combination therapy (including fixed-dose combinations) did not identify any RCTs meeting the systematic review questions posed in the PICOTS format (P=population, I=intervention, C=comparator, O=outcome, T=timing, S=setting). However, in both ACCORD and SPRINT, 2-drug therapy was recommended for most participants in the intensive- but not standard-therapy groups.

Recommendation-Specific Supportive Text

1. Because most patients with hypertension require multiple agents for control of their BP and those with higher BPs are at greater risk, more rapid titration of antihypertensive medications began to be recommended in patients with BP >20/10 mm Hg above their target, beginning with the JNC 7 report (1). In these patients, initiation of antihypertensive therapy with 2 agents is recommended. Evidence favoring this approach comes mostly from studies using fixed-dose combination products showing greater BP lowering with fixed-dose combination agents than with single agents, as well as better adherence to therapy (2, 3). The safety and efficacy of this strategy have been demonstrated in adults to reduce BPs to <140/90 mm Hg though not compared with other strategies (4-6). In general, this approach is reasonable in the very elderly, those at high CVD risk, or those who have a history of hypotension or drug-associated side effects. However, caution is advised in initiating antihypertensive pharmacotherapy with 2 drugs in older patients because hypotension or orthostatic hypotension may develop in some patients; BP should be carefully monitored.

2. The stepped-care approach defined by the initiation of antihypertensive drug therapy with a single agent followed by the sequential titration of the dose and addition of other agents has been the recommended treatment strategy since the first report of the National High Blood Pressure Education Program (7). This approach is also reasonable in the very elderly or those at risk or who have a history of hypotension or drug-
associated side effects. This strategy has been used successfully in nearly all hypertension treatment trials but has not been formally tested against other antihypertensive drug treatment strategies for effectiveness in achieving BP control or in preventing adverse outcomes.

8.2. Achieving BP Control in Individual Patients

Recommendations for lifestyle modifications and drug selection are specified in Sections 6.2, 8.1.4, and 8.1.6. Initial drug selections should be based on trial evidence of treatment efficacy, combined with recognition of compelling indications for use of an agent from a specific drug class, as well as the individual patient’s lifestyle preferences and traits. For a subset of patients (25% to 50%) (1), the initial drug therapy will be well tolerated and effective in achieving the desired level of BP, with only the need for subsequent monitoring (see Section 8.3 for an appropriate follow-up schedule). For others, the initial drug will not be tolerated or will not be effective, requiring either a change in medication or addition of another medication, followed by BP monitoring (2). Approximately 25% of patients will require additional treatment adjustments. In a minority of this group, achievement of goal BP can be challenging.

In patients who do not respond to or do not tolerate treatment with 2 to 3 medications or medication combinations, additional trials of treatment tend to be ineffective or poorly tolerated. Some patients may become disillusioned and lost to follow-up, whereas others will identify an alternative healthcare provider, including nontraditional healers, or will try popular home remedies. Working with this more demanding subset requires provider expertise, patience, and a mechanism to respond efficiently and sensitively to concerns as they arise. In this setting, team-based care (see Section 12) may be effective, encouraging coupling of nonpharmacological and pharmacological treatments, while improving access to and communication with care providers.

In the setting of medication intolerance, consider allowing a defined period of time to evaluate the effects of lifestyle modification in patients with a relatively low CVD risk (10-year risk of ASCVD <10%, based on the ASCVD Risk Estimator [http://tools.acc.org/ASCVD-Risk-Estimator]), with scheduled follow-up visits for assessment of BP levels, including a review of HBPM data, and an appraisal of lifestyle change goal achievements. For patients with a higher level of CVD risk or with significant elevations in BP (SBP or DBP >20 or >10 mm Hg above target, respectively), medication is usually started even while the patient is pursuing lifestyle change (see Section 8.1.2).

Consideration of patient comorbidities, lifestyle, and preferences may suggest better tolerance or greater effect from one class of medication versus other classes. For example, if hyponatremia is present, it would be important to avoid or stop thiazide diuretic therapy. In this case, a loop diuretic should be used if a
Whelton PK, et al.
2017 High Blood Pressure Clinical Practice Guideline

diuretic is required. If hypokalemia is present, primary or secondary aldosteronism should be excluded, after which one should consider a potassium-sparing agent, such as spironolactone, eplerenone, triamterene, or amiloride. In addition, reducing dietary sodium intake will diminish urinary potassium losses. If the patient has chronic cough or a history of ACE inhibitor–induced cough or develops a cough or bronchial responsiveness while on an ACE inhibitor, one should use an ARB in place of an ACE inhibitor. For patients with bronchospastic lung disease, a beta-1-selective blocker (e.g., bisoprolol, metoprolol) should be considered if beta-blocker therapy is required. A patient who is already adherent to lifestyle change recommendations, including diligent reduction in sodium intake, may show a greater response to a RAS blocker. Prior patient experience should be considered, as in the case of cough associated with prior use of an ACE inhibitor, which is likely to recur if an agent from the same class is prescribed.

References

8.3. Follow-Up of BP During Antihypertensive Drug Therapy

Appropriate follow-up and monitoring enable assessment of adherence (see Section 12.1) and response to therapy, help identify adverse responses to therapy and target organ damage, and allow assessment of progress toward treatment goals. High-quality RCTs have successfully and safely developed strategies for follow-up, monitoring, and reassessment from which recommendations can be made (Figure 4) (1, 2). A systematic approach to out-of-office BP assessment is an essential part of follow-up and monitoring of BP, to assess response to therapy; check for evidence of white coat hypertension, white coat effect, masked hypertension, or masked uncontrolled hypertension; and help achieve BP targets (see Sections 4 and 12).

9. Hypertension in Patients With Comorbidities

Certain comorbidities may affect clinical decision-making in hypertension. These include ischemic heart disease, HF with reduced ejection fraction (HFrEF), HFrEF, CKD (including renal transplantation), cerebrovascular disease, AF, PAD, DM, and metabolic syndrome (1). As noted in Section 8.1.2, this guideline generally recommends use of BP-lowering medications for secondary prevention of CVD in patients with clinical CVD (CHD, HF, and stroke) and an average BP ≥130/80 mm Hg and for primary prevention of CVD in adults with an estimated 10-year ASCVD risk of ≥10% and an average SBP ≥130 mm Hg or an average DBP ≥80 mm Hg. Although we recommend use of the ACC/AHA Pooled Cohort Equations (http://tools.acc.org/ASCVD-
Risk-Estimator/) to estimate 10-year risk of ASCVD to establish the BP threshold for treatment, the vast majority of adults with a co-morbidity are likely to have a 10-year risk of ASCVD that exceeds 10%. In some instances, clinical trial confirmation of treatment in patients with comorbidities is limited to a target BP of 140/90 mm Hg. In addition, the selection of medications for use in treating high BP in patients with CVD is guided by their use for other compelling indications (e.g., beta blockers after MI, ACE inhibitors for HFrEF), as discussed in specific guidelines for the clinical condition (2-4). The present guideline does not address the recommendations for treatment of hypertension occurring with acute coronary syndromes.

Synopsis

Hypertension is a major risk factor for ischemic heart disease. Numerous RCTs have demonstrated the benefits of antihypertensive drug therapy in reducing the risk of ischemic heart disease. The following recommendations apply only to management of hypertension in patients with SIHD without HF. See Section 9.2 for recommendations for the treatment of patients with SIHD and HF. Figure 5 is an algorithm on management of hypertension in patients with SIHD.

Recommendation-Specific Supportive Text

1. In patients with increased cardiovascular risk, reduction of SBP to <130/80 mm Hg has been shown to reduce CVD complications by 25% and all-cause mortality by 27% (1).

2. After 5 years of randomized therapy in high-CVD-risk patients, ramipril produced a 22% reduction in MI, stroke, or CVD compared with placebo (10). No added benefit on CVD outcomes was seen when compared with CCBs and diuretics (15, 16). After 4.2 years of randomized therapy in patients with SIHD, perindopril reduced CVD death, MI, or cardiac arrest by 20% compared with placebo (7). Beta blockers are effective drugs for preventing angina pectoris, improving exercise time until the onset of angina pectoris, reducing exercise-induced ischemic ST-segment depression, and preventing coronary events (8, 17-22). Because of their compelling indications for treatment of SIHD, these drugs are recommended as a first-line therapy in the treatment of hypertension when it occurs in patients with SIHD. GDMT beta blockers for SIHD that are also effective in lowering BP include carvedilol, metoprolol tartrate, metoprolol succinate, nadolol, bisoprolol, propranolol, and timolol. Atenolol is not as effective as other antihypertensive drugs in the treatment of hypertension (23).

3. Dihydropyridine CCBs are effective antianginal drugs that can lower BP and relieve angina pectoris when added to beta blockers in patients in whom hypertension is present and angina pectoris persists despite beta-blocker therapy (8, 17, 19-22, 24, 25). GDMT beta blockers for SIHD that are also effective in lowering BP include carvedilol, metoprolol tartrate, metoprolol succinate, nadolol, bisoprolol, propranolol, and timolol.

4. In randomized long-term trials, use of beta blockers after MI reduced all-cause mortality by 23% (13). Given the established efficacy of beta blockers for treating hypertension and SIHD, their use for treatment continuing beyond 3 years after MI is reasonable (6, 25).

5. GDMT beta blockers and CCBs are effective antihypertensive and antianginal agents. CCBs include dihydropyridine and nondihydropyridine agents. CCBs can be used separately or together with beta blockers beginning 3 years after MI in patients with CAD who have both hypertension and angina.

</tr>
</tbody>
</table>

Synopsis

Antecedent hypertension is present in 75% of patients with chronic HF (4). In the Cardiovascular Health Study (5) and the Health, Aging and Body Composition Study (6), 11.2% of 4408 persons (53.1% women, with a mean age of 72.8 years, living in the community, and not receiving antihypertensive drugs at baseline) developed HF over 10 years (7). Compared with those with an average SBP <120 mm Hg, the adjusted incidence of HF was increased 1.6, 2.2, and 2.6 times in those with average SBPs between 120 and 139 mm Hg, between 140 and 159 mm Hg, and ≥160 mm Hg, respectively (7).

No RCTs are available that compare one BP-lowering agent to another for the management of patients with HF. The following recommendations for treatment of hypertension in HF are based on use of drugs that lower BP and also have compelling indications for management of HF (with HFREF or HFrEF) as recommended in current ACC/AHA guidelines (4, 8).

Recommendation-Specific Supportive Text

1. In adults with hypertension (SBP ≥130 mm Hg or DBP ≥80 mm Hg) and a high risk of CVD, a strong body of evidence supports treatment with antihypertensive medications (see Section 8.1.2) and more-intensive rather than less-intensive intervention (see Section 8.1.5). In SPRINT, a more intensive intervention that targeted an SBP <120 mm Hg significantly reduced the primary outcome (CVD composite) by about 25% (9). The incidence of HF, a component of the primary outcome, was also substantially decreased (hazard ratio: 0.62; 95% confidence interval: 0.45–0.84). Meta-analyses of clinical trials have identified a similar beneficial effect of more-intensive BP reduction on the incidence of HF (2, 10), but the body of information from studies confined to trials that randomly assigned participants to different BP targets is more limited and less compelling (3). In addition, the available trials were efficacy studies in which BP measurements were more consistent with guideline recommendations than is common in clinical practice, resulting in lower absolute values for SBP. For both of these reasons, the SBP target recommended during BP lowering (<130 mm Hg) is higher than that used in SPRINT.

<td>1. Adults with HFrEF and hypertension should be prescribed GDMT (2) titrated to attain a BP of less than 130/80 mm Hg.</td>
</tr>
<tr>
<td>III: No Benefit</td>
<td>B-R</td>
<td>2. Nondihydropyridine CCBs are not recommended in the treatment of hypertension in adults with HFrEF (1).</td>
</tr>
</tbody>
</table>

**Synopsis**

Approximately 50% of patients with HF have HFrEF (2-6). Numerous RCTs have shown that treatment of HFrEF with GDMT reduces mortality and HF hospitalizations (7). Large-scale RCTs have shown that antihypertensive drug therapy reduces the incidence of HF in patients with hypertension (8-11). In ALLHAT (Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial), chlorthalidone reduced the risk of HFrEF more than amlodipine and doxazosin but similarly to lisinopril (12, 13).

**Recommendation-Specific Supportive Text**

1. This recommendation is based on guidance in the 2017 ACC/AHA/HFSA guideline focused update on heart failure (14) (see figure from the HF focused update that is reproduced in Online Data Supplement A). Lifestyle modification, such as weight loss and sodium reduction, may serve as adjunctive measures to help these agents work better. No RCT evidence is available to support the superiority of one BP-lowering medication with compelling indications for treatment of HFrEF over another. Medications with compelling indications for HF that may be used as first-line therapy to treat high BP include ACE inhibitors or ARBs, angiotensin receptor-neprilysin inhibitors, mineralocorticoid receptor antagonists, diuretics, and GDMT beta blockers ( carvedilol, metoprolol succinate, or bisoprolol).

   Clinical trials evaluating goal BP reduction and optimal BP-lowering agents in the setting of HFrEF and concomitant hypertension have not been performed. However, in patients at higher CVD risk, BP lowering is associated with fewer adverse cardiovascular events (7). GDMT for HFrEF with agents known to lower BP should consider a goal BP reduction consistent with a threshold now associated with improved clinical outcomes but not yet proven by RCTs in an HF population.
2. Nondihydropyridine CCBs (verapamil, diltiazem) have myocardial depressant activity. Several clinical trials have demonstrated either no clinical benefit or even worse outcomes in patients with HF treated with these drugs (1). Therefore, nondihydropyridine CCBs are not recommended in patients with hypertension and HFrEF.

Synopsis

Approximately 50% of patients with HF have HFpEF (2, 7-11). The ejection fraction in these studies has varied from >40% to ≥55% (2). Patients with HFpEF are usually older women with a history of hypertension. Obesity, CHD, DM, AF, and hyperlipidemia are also highly prevalent in patients with HFpEF (2, 11, 12). Hypertension is the most important cause of HFpEF, with a prevalence of 60% to 89% in large RCTs, epidemiological studies, and HF registries (2, 13). Patients with HFpEF also have an exaggerated hypertensive response to exercise (14). Hypertensive acute pulmonary edema is an expression of HFpEF (15).

BP control is important for prevention of HFpEF in patients with hypertension (2, 16-19). ALLHAT showed that treatment of hypertension with chlorthalidone reduced the risk of HF compared with amlopidine, doxazosin, and lisinopril (19, 20). Improved BP control also reduces hospitalization, CVD events, and mortality (2, 16-19).

Recommendation-Specific Supportive Text

1. Diuretics are the only drugs used for the treatment of hypertension and HF that can adequately control the fluid retention of HF. Appropriate use of diuretics is also crucial to the success of other drugs used for the treatment of hypertension in the presence of HF. The use of inappropriately low doses of diuretics can result in fluid retention. Conversely, the use of inappropriately high doses of diuretics can lead to volume contraction, which can increase the risk of hypotension and renal insufficiency. Diuretics should be prescribed to all patients with hypertension and HFpEF who have evidence of, and to most patients with a prior history of, fluid retention.

2. In a trial of patients with HFpEF and MI, patients randomized to propranolol had at 32-month follow-up a 35% reduction in mortality rate (3). After 21 months of treatment in patients with HFrEF and HFpEF, compared with placebo, those randomized to nebivolol had a 14% reduction in mortality or CVD hospitalization if they had HFrEF and a 19% reduction if they had HFpEF (4). In patients with HFpEF, the primary outcome (a composite of CVD death or HF hospitalization) was observed in 22% for candesartan and 24% for placebo (11% reduction), but fewer patients receiving candesartan were hospitalized for HF (5). The use of nitrates in the setting of HFpEF is associated with a signal of harm and in most situations should be avoided. For many other common antihypertensive agents, including alpha blockers, beta blockers, and calcium channel blockers, limited data exist to guide the choice of antihypertensive therapy in the setting of HFpEF (21). Renin-angiotensin-aldosterone system inhibition, however, with ACE inhibitor or ARB and especially MRA would represent the preferred choice. A shared decision-making discussion, with the patient influenced by clinician judgment, should drive the ultimate choice of antihypertensive agents.

### Synopsis

Refer to the “Systematic Review for the 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults” for the complete systematic evidence review for additional data and analyses (13). Hypertension is the most common comorbidity affecting patients with CKD. Hypertension has been reported in 67% to 92% of patients with CKD, with increasing prevalence as kidney function declines (14). Hypertension may occur as a result of kidney disease, yet the presence of hypertension may also accelerate further kidney injury; therefore, treatment is an important means to prevent further kidney functional decline. This tight interaction has led to extensive debate about the optimal BP target for patients with CKD (15-18). Masked hypertension may occur in up to 30% of patients with CKD and portends higher risk of CKD progression (19-23). CKD is an important risk factor for CVD (24), and the coexistence of hypertension and CKD further increases the risk of adverse CVD and cerebrovascular events, particularly when proteinuria is present (25). Even as the importance of hypertension treatment is widely accepted, data supporting BP targets in CKD are limited, as patients with CKD were historically excluded from clinical trials. Furthermore, CKD is not included in the CVD risk calculations used to determine suitability for most clinical trials (26-28).

Until publication of the SPRINT results, most guidelines for BP targets in patients with CKD favored treatment to a BP <140/90 mm Hg (15), with consideration of the lower target of <130/80 mm Hg for those with more severe proteinuria (≥300 mg albuminuria in 24 hours or the equivalent), if tolerated (16-18). Patients with stage 3 to 4 CKD (eGFR of 20 to <60 mL/minute/1.73 m²) comprised 28% of the SPRINT study population, and in this group intensive BP management seemed to provide the same benefits for reduction in the CVD composite primary outcome and all-cause mortality as were seen in the full study cohort. Given that most patients with CKD die from CVD complications, this RCT evidence supports a lower target of <130/80 mm Hg for all patients with CKD (Figure 6). It is appropriate to acknowledge that many patients with CKD have additional comorbidities and evidence of frailty that caused them to be excluded from past clinical trials. Observational studies of CKD cohorts indicate a higher risk of mortality at lower systolic pressures and a flat relationship of SBP to event risk in elderly patients with CKD (29, 30), which supports concerns that these complex patients may be at greater risk of complications from intensive BP treatment and may fail to achieve benefits from lower BP targets. In contrast, in the prespecified subgroup analysis of the elderly cohort in...
SPRINT, frail elderly patients did sustain benefit from the lower BP target, which supports a lower goal for all patients, including those with CKD (31). In this setting, incremental BP reduction may be appropriate, with careful monitoring of physical and kidney function.

An ACE inhibitor (or an ARB, in case of ACE inhibitor intolerance) is a preferred drug for treatment of hypertension if albuminuria (≥300 mg/day or ≥300 mg/g creatinine by first morning void) is present, although the evidence is mixed (10, 11) (Figure 6). In the course of reducing intraglomerular pressure and thereby reducing albuminuria, serum creatinine may increase up to 30% because of concurrent reduction in GFR (32). Further GFR decline should be investigated and may be related to other factors, including volume contraction, use of nephrotoxic agents, or renovascular disease (33). The combination of an ACE inhibitor and an ARB should be avoided because of reported harms demonstrated in several large cardiology trials (34, 35) and in 1 diabetic nephropathy trial (36). Because of the greater risk of hyperkalemia and hypotension and lack of demonstrated benefit, the combination of an ARB (or ACE inhibitor) and a direct renin inhibitor is also contraindicated during management of patients with CKD (37).

Figure 6 is an algorithm on management of hypertension in patients with CKD.

**Recommendation-Specific Supportive Text**

1. We recommend ASCVD risk assessment in all adults with hypertension, including those with CKD. As a matter of convenience, however, it can be assumed that the vast majority of patients with CKD have a 10-year ASCVD risk ≥10%, placing them in the high risk category that requires initiation of antihypertensive drug therapy at BP ≥130/80 mm Hg (see Section 8.1.2, Figure 4 and Table 23 for BP thresholds for initiating antihypertensive drug treatment). In SPRINT, the participants with CKD who were randomized to intensive antihypertensive therapy (SBP target <120 mm Hg) appeared to derive the same beneficial reduction in CVD events and all-cause mortality that was seen in their counterparts without CKD at baseline. Likewise, intensive therapy was beneficial even in those ≥75 years of age with frailty or the slowest gait speed. There was no difference in the principal kidney outcome (≥50% decline in eGFR or ESRD) between the intensive-and standard-therapy (SBP target <140 mm Hg) groups (26). Three other RCTs (1-3) have evaluated the effect of differing BP goals of <140/90 mm Hg versus 125–130/75–80 mm Hg on CKD progression in patients with CKD. None of these trials demonstrated a benefit for more intensive BP reduction, although post hoc follow-up analyses favored the lower targets in patients with more severe proteinuria (38, 39), and these trials were underpowered to detect differences in CVD event rates. Recent meta-analyses and systematic reviews that included patients with CKD from SPRINT support more intensive BP treatment (40-42) to reduce cardiovascular events but do not demonstrate a reduction in the rate of progression of kidney disease (doubling of serum creatinine or reaching ESRD). More intensive BP treatment may result in a modest reduction in GFR, which is thought to be primarily due to a hemodynamic effect and may be reversible. Electrolyte abnormalities are also more likely during intensive BP treatment. More intensive BP lowering in patients with CKD is also supported by a BP Lowering Treatment Trialists’ Collaboration meta-analysis of RCTs in patients with CKD (43).

2. Evidence comes from AASK (The African American Study of Kidney Disease and Hypertension), 2 small trials (1 positive, 1 negative), and a meta-analysis (3, 6, 10, 11). Albuminuria is quantified by 24-hour urine collection. A 10% to 25% increase in serum creatinine may occur in some patients with CKD as a result of ACE inhibitor therapy.

3. ARBs were shown to be noninferior to ACE inhibitors in clinical trials in the non-CKD population (35). A 10% to 25% increase in serum creatinine may occur in some patients with CKD as a result of ARB therapy.
Figure 6. Management of Hypertension in Patients With CKD

Colors correspond to Class of Recommendation in Table 1.
*CKD stage 3 or higher or stage 1 or 2 with albuminuria ≥300 mg/d or ≥300 mg/g creatinine.
ACE indicates angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP blood pressure; and CKD, chronic kidney disease.

<tr>
<td>Ila</td>
<td>B-R</td>
<td>2. After kidney transplantation, it is reasonable to treat patients with hypertension with a calcium antagonist on the basis of improved GFR and kidney survival (2).</td>
</tr>
</tbody>
</table>

**Synopsis**

After kidney transplantation, hypertension is common because of preexisting kidney disease, the effects of immunosuppressive medications, and the presence of allograft pathology (3). Transplant recipients frequently harbor multiple CVD risk factors and are at high risk of CVD events. Hypertension may accelerate target organ damage and kidney function decline, particularly when proteinuria is present (4-6).

Use of calcineurin inhibitor–based immunosuppression regimens after transplantation is associated with a high (70% to 90%) prevalence of hypertension (7). Hypertension is less common when calcineurin inhibitors have been used without corticosteroids in liver transplantation patients (8), although prevalence rates have not differed in steroid minimization trials after kidney transplantation (9, 10). Reports from long-term belatacept-based immunosuppression studies indicate higher GFR and preservation of kidney function. However, hypertension was still present in the majority of patients, although fewer agents were needed to achieve BP goals (11). Severity of hypertension and intensity of treatment may differ somewhat depending on the type of organ transplanted; however, most concepts relevant to kidney transplant recipients will apply to the other solid organ recipients as well.

BP targets change over time after transplantation. Initially, it is important to maintain ample organ perfusion with less stringent BP targets (<160/90 mm Hg) to avoid hypotension and risk of graft thrombosis. Beyond the first month, BP should be controlled to prevent target organ damage as in the nontransplantation setting (12, 13). Hypertension after transplantation is often associated with altered circadian BP rhythm with loss of the normal nocturnal BP fall (14, 15) and, in some, a nocturnal BP rise. These changes may return to normal after a longer period of follow-up (16).

**Recommendation-Specific Supportive Text**

1. Although treatment targets for hypertension after transplantation should probably be similar to those for other patients with CKD, there are no trials in post-transplantation patients comparing different BP targets. As kidney transplant recipients generally have a single functioning kidney and CKD, BP targets should be similar to those for the general CKD population.

2. Limited studies have compared drug choice for initial antihypertensive therapy in patients after kidney transplantation. On the basis of a Cochrane analysis (2), most studies favor CCBs to reduce graft loss and maintain higher GFR, with some evidence suggesting potential harm from ACE inhibitors because of anemia, hyperkalemia, and lower GFR. In recognition of this concern, RAS inhibitors may be reserved for the subset of patients with hypertension and additional comorbidities that support the need for ACE inhibitor therapy (i.e., proteinuria or HF after transplantation). With appropriate potassium and creatinine monitoring, this has been demonstrated to be safe (17).
9.4. Cerebrovascular Disease

Stroke is a leading cause of death, disability, and dementia (1). Because of its heterogeneous causes and hemodynamic consequences, the management of BP in adults with stroke is complex and challenging (2). To accommodate the variety of important issues pertaining to BP management in the stroke patient, treatment recommendations require recognition of stroke acuity, stroke type, and therapeutic objectives. Future studies should target more narrowly defined questions, such as optimal BP-reduction timing and target, as well as ideal antihypertensive agent therapeutic class by patient type and event type.

<td></td>
<td>2. Immediate lowering of SBP (Table 19) to less than 140 mm Hg in adults with spontaneous ICH who present within 6 hours of the acute event and have an SBP between 150 mm Hg and 220 mm Hg is not of benefit to reduce death or severe disability and can be potentially harmful (1, 2).</td>
</tr>
</tbody>
</table>

Synopsis

Spontaneous, nontraumatic ICH is a significant global cause of morbidity and mortality (3). Elevated BP is highly prevalent in the setting of acute ICH and is linked to greater hematoma expansion, neurological worsening, and death and dependency after ICH.

Figure 7 is an algorithm on management of hypertension in patients with acute ICH.

Recommendation-Specific Supportive Text

1. Information about the safety and effectiveness of early intensive BP-lowering treatment is least well established for patients with markedly elevated BP (sustained SBP >220 mm Hg) on presentation, patients with large and severe ICH, or patients requiring surgical decompression. However, given the consistent nature of the data linking high BP with poor clinical outcomes (4-6) and some suggestive data for treatment in patients with modestly high initial SBP levels (1, 7), early lowering of SBP in ICH patients with markedly high SBP levels (>220 mm Hg) might be sensible. A secondary endpoint in 1 RCT and an overview of data from 4 RCTs indicate that intensive BP reduction, versus BP-lowering guideline treatment, is associated with greater functional recovery at 3 months (1, 7).

2. RCT data have suggested that immediate BP lowering (to <140/90 mm Hg) within 6 hours of an acute ICH was feasible and safe (1, 8, 9), may be linked to greater attenuation of absolute hematoma growth at 24 hours (7), and might be associated with modestly better functional recovery in survivors (1, 7). However, a recent RCT (2) that examined immediate BP lowering within 4.5 hours of an acute ICH found that treatment to achieve a target SBP of 110 to 139 mm Hg did not lead to a lower rate of death or disability than standard reduction to a target of 140 to 179 mm Hg. Moreover, there were significantly more renal adverse events within 7 days after randomization in the intensive-treatment group than in the standard-treatment group (2). Put together, neither of the 2 key trials (1, 2) evaluating the effect of lowering SBP in the acute period after spontaneous ICH met their primary outcomes of reducing death and severe disability at 3 months.

</tr>
</tbody>
</table>

### Synopsis

Elevated BP is common during acute ischemic stroke (occurring in up to 80% of patients), especially among patients with a history of hypertension (10). However, BP often decreases spontaneously during the acute phase of ischemic stroke, as soon as 90 minutes after the onset of symptoms. Countervailing theoretical concerns about arterial hypertension during acute ischemic stroke include aiming to enhance cerebral perfusion of the ischemic tissue while minimizing the exacerbation of brain edema and hemorrhagic transformation of the ischemic tissue (11, 12). Some studies have shown a U-shaped relationship between the admission BP and favorable clinical outcomes, with an optimal SBP and DBP ranging from 121 to 200 mm Hg and 81 to 110 mm Hg, respectively (13). It is conceivable that an optimal arterial BP range exists during acute ischemic stroke on an individual basis, contingent on the ischemic stroke subtype and other patient-specific comorbidities. Early initiation or resumption of antihypertensive treatment after acute ischemic stroke is indicated only in specific situations: 1) patients treated with tissue-type plasminogen activator (1, 2), and 2) patients with SBP >220 mm Hg or DBP >120 mm Hg. For the latter group, it should be kept in mind that cerebral autoregulation in the ischemic penumbra of the stroke is grossly abnormal and that systemic perfusion pressure is needed for blood flow and oxygen delivery. Rapid reduction of BP, even to lower levels within the hypertensive range, can be detrimental. For all other acute ischemic stroke patients, the advantage of lowering BP early to reduce death and dependency is uncertain (4-9), but restarting antihypertensive therapy...
to improve long-term BP control is reasonable after the first 24 hours for patients who have preexisting hypertension and are neurologically stable (4, 5, 14, ).

Figure 8 is an algorithm on management of hypertension in patients with acute ischemic stroke.

Recommendation-Specific Supportive Text

1. These BP cutoffs correspond to study inclusion criteria in pivotal clinical trials of intravenous thrombolysis for acute ischemic stroke (1).

2. In a large observational study of patients with acute ischemic stroke who received intravenous tissue-type plasminogen activator, high BP during the initial 24 hours was linked to greater risk of symptomatic ICH (3).

3. For the goal of antihypertensive therapy, see Section 8.1.5.

4. Extreme arterial hypertension is detrimental because it can lead to encephalopathy, cardiac compromise, and renal damage. However, hypotension, especially when too rapidly achieved, is potentially harmful because it abruptly reduces perfusion to multiple organs, including the brain.

5. Data from 2 RCTs (5, 9), as well as systematic reviews and meta-analyses (6-8), indicate that antihypertensive agents reduce BP during the acute phase of an ischemic stroke but do not confer benefit with regard to short- and long-term dependency and mortality rate. One RCT did not demonstrate a benefit of continuing prestroke antihypertensive drugs during the first few days after an acute stroke, but it was substantially underpowered to answer the question (4).
Acute (<72 h from symptom onset) ischemic stroke and elevated BP

Yes

Patient qualifies for IV thrombolysis therapy

BP ≤220/110 mm Hg

Initiating or reinitiating treatment of hypertension within the first 48-72 hours after an acute ischemic stroke is ineffective to prevent death or dependency (Class III: No Benefit)

BP >220/110 mm Hg

Lower BP 15% during first 24 h (Class IIb)

No

Lower SBP to <185 mm Hg and DBP <110 mm Hg before initiation of IV thrombolysis (Class I)

Maintain BP <180/105 mm Hg for first 24 h after IV thrombolysis (Class I)

For preexisting hypertension, reinitiate antihypertensive drugs after neurological stability (Class IIa)

Colors correspond to Class of Recommendation in Table 1.

BP indicates blood pressure; DBP, diastolic blood pressure; IV, intravenous; and SBP, systolic blood pressure.

</table>

**Synopsis**

Each year in the United States, >750,000 adult patients experience a stroke, of which up to 25% are recurrent strokes (10). For an individual who experiences an initial stroke or TIA, the annual risk of a subsequent or
“secondary” stroke is approximately 4% (11), and the case mortality rate is 41% after a recurrent stroke versus 22% after an initial stroke (12). Among patients with a recent stroke or TIA, the prevalence of premorbid hypertension is approximately 70% (13). Risk of recurrent stroke is heightened by presence of elevated BP, and guideline-recommended antihypertensive drug treatment to lower BP has been linked to a reduction in 1-year recurrent stroke risk (14). RCT meta-analyses show an approximately 30% decrease in recurrent stroke risk with BP-lowering therapies (1-3). An issue frequently raised by clinicians is whether the presence of clinically asymptomatic cerebral infarction incidentally noted on brain imaging (computed tomography or MRI scan) in patients without a history of or symptoms of a stroke or TIA warrants implementation of secondary stroke prevention measures. Clinically asymptomatic vascular brain injury is increasingly being considered as an entry point for secondary stroke prevention therapies, because these apparently “silent” brain infarctions are associated with typical stroke risk factors, accumulatively lead to subtle neurological impairments, and bolster risk of future symptomatic stroke events (15). Although the evidence for using antihypertensive treatment to prevent recurrent stroke in stroke patients with elevated BP is compelling (1-3), questions remain about when precisely after an index stroke to initiate it, what specific agent(s) to use (if any), which therapeutic targets to aim for, and whether the treatment approach should vary by index stroke mechanism and baseline level of BP (16).

Figure 9 is an algorithm on management of hypertension in patients with a previous history of stroke (secondary stroke prevention).

Recommendation-Specific Supportive Text

1. Two overviews of RCTs published through 2009 showed that antihypertensive medications lowered the risk of recurrent vascular events in patients with stroke or TIA (1-3).

2. Specific agents that have shown benefit in either dedicated RCTs or systematic reviews of RCT data include diuretics, ACE inhibitors, and ARBs.

3. Support for this recommendation is based on data from 2 dedicated RCTs, as well as a systematic review and meta-analysis, among patients with a history of stroke or TIA (1-3).

4. Reduction in BP appears to be more important than the choice of specific agents used to achieve this goal. Thus, if diuretic and ACE inhibitor or ARB treatment do not achieve BP target, other agents, such as CCB and/or mineralocorticoid receptor antagonist, may be added.

5. An overview of RCTs showed that larger reductions in SBP tended to be associated with greater reduction in risk of recurrent stroke. However, a separate overview of RCTs in patients who experienced a stroke noted that achieving an SBP level <130 mm Hg was not associated with a lower stroke risk, and several observational studies did not show benefit with achieved SBP levels <120 mm Hg (5).

6. Patients with a lacunar stroke treated to an SBP target of <130 mm Hg versus 130 to 140 mm Hg may be less likely to experience a future ICH.

7. No published RCTs have specifically addressed this question, but a post hoc analysis of an RCT suggests that the effectiveness of antihypertensive treatment for secondary stroke prevention diminishes as initial baseline BP declines (9).
Figure 9. Management of Hypertension in Patients With a Previous History of Stroke (Secondary Stroke Prevention)

Colors correspond to Class of Recommendation in Table 1.
DBP indicates diastolic blood pressure; SBP, systolic blood pressure; and TIA, transient ischemic attack.

**9.5. Peripheral Arterial Disease**

| Recommendation for Treatment of Hypertension in Patients With PAD |
|-------------------------|-------------------------|
| References that support the recommendation are summarized in Online Data Supplement 45. |
| COR | LOE | Recommendation |
| I | B-NR | Adults with hypertension and PAD should be treated similarly to patients with hypertension without PAD (1-4). |

**Synopsis**

Patients with PAD are at increased risk of CVD and stroke. Hypertension is a major risk factor for PAD, so these patients are commonly enrolled in trials of antihypertensive drug therapy. However, patients with PAD typically comprise a small fraction of participants, so in the few trials that report results in patients with PAD, subgroup analyses are generally underpowered.

**Recommendation-Specific Supportive Text**

1. There is no major difference in the relative risk reduction in CVD from BP-lowering therapy between patients with hypertension and PAD and patients without PAD (1). There is also no evidence that any one class of antihypertensive medication or strategy is superior (2-4). In the INVEST (International Verapamil-Trandolapril) study, the beta blocker atenolol (with or without hydrochlorothiazide) was compared with the CCB verapamil (with or without perindopril). The study showed no significant difference in CVD outcomes between the 2 drug regimens in patients with and without PAD (3). No trials have reported the effects of a higher versus a lower BP goal in patients with PAD. In the 1 trial (ALLHAT) that reported the effects of different classes of BP medications on PAD as an outcome, there was no significant difference by medication class (5).

SR indicates systematic review.

**Synopsis**

Refer to the “Systematic Review for the 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults” for the complete systematic evidence review for additional data and analyses (13). The prevalence of hypertension among adults with DM is approximately 80%, and hypertension is at least twice as common in persons with type 2 DM than in age-matched individuals without DM (14-16). The coexistence of hypertension and DM markedly increases the risk of developing CVD damage, resulting in a higher incidence of CHD, HF, PAD, stroke, and CVD mortality (17), and may increase risk of microvascular disease, such as nephropathy or retinopathy (16, 18).

There is limited quality evidence to determine a precise BP target in adults with DM. No RCTs have explicitly 1) documented whether treatment to an SBP goal <140 mm Hg versus a higher goal improves clinical outcomes in adults with hypertension and DM or 2) directly evaluated clinical outcomes associated with SBP <130 mm Hg (2). However, 2 high-quality systematic reviews of RCTs support an SBP target of <140 mm Hg (4, 7).

There is little or no available RCT evidence supporting a specific DBP threshold for initiation of pharmacological therapy. Several RCTs, including the HOT (Hypertension Optimal Treatment) trial, UKPDS (United Kingdom Prospective Diabetes Study), and ABCD (Appropriate Blood Pressure Control in Diabetes) trial (19-22), are often cited to support a lower DBP target (e.g., ≤85 or 80 mm Hg) for adults with hypertension and DM. However, these trials were conducted when the diagnostic criteria for DM were more conservative than they are currently (2 fasting glucose levels >140 mg/dL as opposed to 126 mm/dL today).
Recommendation-Specific Supportive Text

1. We recommend ASCVD risk assessment in all adults with hypertension, including adults with DM. As a matter of convenience, however, it can be assumed that the vast majority of adults with DM have a 10-year ASCVD risk ≥ 10%, placing them in the high risk category that requires initiation of antihypertensive drug therapy at BP ≥ 130/80 mm Hg (see Section 8.1.2, Figure 4 and Table 23 for BP thresholds for initiating antihypertensive drug treatment). The ACCORD trial (5), which compared CVD outcomes in adults with DM and hypertension who were randomized to an SBP target of <140 mm Hg (standard therapy) or <120 mm Hg (intensive therapy), did not document a significant reduction in the primary outcome (CVD composite) with the lower BP goal, but the trial was underpowered to detect a statistically significant difference between the 2 treatment arms. The ACCORD trial demonstrated a small reduction in absolute risk (1.1%) for stroke, but there were few such events. More adverse events (2% increase in absolute risk) were identified in the lower BP group, especially self-reported hypotension and a reduction in estimated GFR, but these did not result in an excess of stroke or ESRD. The ACCORD trial was a factorial study; secondary analysis demonstrated a significant outcome benefit in the intensive BP/standard glycemic group (3), but benefit in the intensive BP/intensive glycemic control group was no better than in the intensive BP/standard glycemic control group, which suggests a floor benefit beyond which the combined intensive interventions were ineffective (5). An ACCORD secondary analysis suggested that an SBP <120 mm Hg is superior to standard BP control in reducing LVH (6).

   A meta-analysis of 73,913 patients with DM reported that an SBP <130 mm Hg reduced stroke by 39%. However, there was no significant risk reduction for MI (23). Two meta-analyses addressing target BP in adults with DM restricted the analysis to RCTs that randomized patients to different BP levels (4, 7). Target BP of 133/76 mm Hg provided significant benefit compared with that of 140/81 mm Hg for major cardiovascular events, MI, stroke, albuminuria, and retinopathy progression (4). Several meta-analyses of RCTs included all trials with a difference in BP (24, 25), but 2 restricted their analyses to trials in which participants were randomized to different BP target levels (4, 7).

   SPRINT demonstrated cardiovascular benefit from intensive treatment of BP to a goal of <120 mm Hg as compared with <140 mm Hg but did not include patients with DM. However, the results of ACCORD and SPRINT were generally consistent (26). In addition, a SPRINT substudy demonstrated that patients with prediabetes derived a benefit similar to that of patients with normoglycemia (8). Previous trials have shown similar quantitative benefits from lowering BP in persons with and without DM (9).

2. BP control is more difficult to achieve in patients with DM than in those without DM, necessitating use of combination therapy in the majority of patients (27). All major antihypertensive drug classes (i.e., ACE inhibitors, ARBs, CCBs, and diuretics) are useful in the treatment of hypertension in DM (1, 9). However, in ALLHAT, doxazosin was clearly inferior to chlorthalidone, which also reduced some events more than amlodipine or lisinopril (28).

3. ACE inhibitors and ARBs have the best efficacy among the drug classes on urinary albumin excretion (12) (see Section 9.3). Therefore, an ACE inhibitor or ARB may be considered as part of the combination. A meta-analysis of RCTs of primary prevention of albuminuria in patients with DM demonstrated a significant reduction in progression of moderately to severely increased albuminuria with the use of ACE inhibitors or ARBs (11).

References

9.7. Metabolic Syndrome

Metabolic syndrome is a state of metabolic dysregulation characterized by visceral fat accumulation, insulin resistance, hyperinsulinemia, and hyperlipidemia, as well as predisposition to type 2 DM, hypertension, and atherosclerotic CVD (1-3). According to data from the NHANES III and NHANES 1999–2006 (1, 4), the prevalence of metabolic syndrome in the United States was 34.2% in 2006 and has likely increased substantially since that time. The metabolic syndrome is linked to several other disorders, including nonalcoholic steatohepatitis, polycystic ovary syndrome, certain cancers, CKD, Alzheimer’s disease, Cushing’s syndrome, lipodystrophy, and hyperalimentation (5, 6).

Lifestyle modification, with an emphasis on improving insulin sensitivity by means of dietary modification, weight reduction, and exercise, is the foundation of treatment of the metabolic syndrome. The optimal antihypertensive drug therapy for patients with hypertension in the setting of the metabolic syndrome has not been clearly defined (1). Although caution exists with regard to the use of thiazide diuretics in this population because of their ability to increase insulin resistance, dyslipidemia, and hyperuricemia and to accelerate conversion to overt DM, no data are currently available demonstrating deterioration in cardiovascular or renal outcomes in patients treated with these agents (1). Indeed, as shown in follow-up of ALLHAT, chlorthalidone use was associated with only a small increase in fasting glucose levels (1.5–4.0 mg/dL), and this increase did not translate into increased CVD risk at a later date (7-10). In addition, in post hoc analysis of the nearly two thirds of participants in ALLHAT that met criteria for the metabolic syndrome, chlorthalidone was unsurpassed in reducing CVD and renal outcomes compared with lisinopril, amlodipine, or doxazosin (9, 11). Similarly, high-dose ARB therapy reduces arterial stiffness in patients with hypertension with the metabolic syndrome, but no outcomes data are available from patients in which this form of treatment was used (12). Use of traditional beta blockers may lead to dyslipidemia or deterioration of glucose tolerance, and ability to lose weight (2). In several large clinical trials, the risk of developing DM as a result of traditional beta-blocker therapy was 15% to 29% (2). However, the newer vasodilating beta blockers (e.g., labetalol, carvedilol, nebivolol) have shown neutral or favorable effects on metabolic profiles compared with the traditional beta blockers (13). Trials using vasodilator beta blockers have not been performed to demonstrate effects on CVD outcomes.

**Synopsis**

AF and hypertension are common and often coexistent conditions, both of which increase in frequency with age. AF occurs in 3% to 4% of the population >65 years of age (3). Hypertension is present in more than 80% of patients with AF and by far the most common comorbid condition, regardless of age (4). AF is associated with systemic thromboembolism, as recognized in the CHADS2 and CHA2DS2-VASc scoring systems for stroke risk (5). It is also associated with gradual worsening of ventricular function, the subsequent development of HF, and increased mortality.

Hypertension has long been recognized as a risk factor for AF because it is associated with LVH, decreased diastolic function with impaired LV filling, rising left atrial pressures with left atrial hypertrophy and enlargement, increased atrial fibrosis, and slowing of intra-atrial and interatrial electrical conduction velocities. Such a distortion of atrial anatomy and physiology increases the incidence of AF (6). Left atrial pressure also increases with ischemic or valvular heart disease and myopathies that are often associated with systemic hypertension, potentially leading to AF.

Although management of AF will continue to revolve around restoration of sinus rhythm when appropriate, rate control when it is not, and anticoagulation, control of hypertension is a key component of therapy (1, 2).

Treatment of hypertension may prevent new-onset AF, especially in patients with LVH or LV dysfunction (1). Five RCTs have compared the value of antihypertensive agents for reduction of new-onset AF (7-11). One study suggested superiority of RAS blockade over a CCB (8), and another reported superiority of RAS blockade over a beta blocker that is no longer recommended for treatment of hypertension (9). In the largest trial, there was no difference in incident AF among adults with hypertension assigned to first-step therapy with a diuretic, ACE inhibitor, or CCB (10). In ALLHAT, the incidence of AF was 23% higher during first-step antihypertensive therapy with the alpha-receptor blocker doxazosin than with chlorthalidone. Furthermore, the occurrence of AF or atrial flutter during the study, either new onset or recurrent, was associated with an increase in mortality of nearly 2.5-fold (10).
Recommendation-Specific Supportive Text

1. Although RAS blockade in theory is the treatment of choice for hypertension in patients with prior AF, relative to other classes of agents, all of the trials that have shown clinical superiority of ARBs over other agents were comparisons with CCBs or beta blockers that are no longer recommended as first-line agents for treatment of hypertension (2). There are no available trials comparing ACE inhibitors with other drugs or any RAS-blocking agents with diuretics.

</tr>
</tbody>
</table>

Recommendation-Specific Supportive Text

1. Hypertension is a risk factor for the development of aortic stenosis (stage A [e.g., aortic sclerosis or bicuspid aortic valve]) and asymptomatic aortic stenosis (stage B [progressive asymptomatic aortic stenosis]). The
combination of hypertension and aortic stenosis, “2 resistors in series,” increases the rate of complications. In patients with asymptomatic mild-to-moderate aortic stenosis, hypertension has been associated with more abnormal LV structure and increased cardiovascular morbidity and mortality (1). There is no evidence that antihypertensive medications will produce an inordinate degree of hypotension in patients with aortic stenosis. Nitroprusside infusion in hypertensive patients with severe aortic stenosis lowers pulmonary and systemic resistance, with improvements in stroke volume and LV end-diastolic pressure (2). Thus, careful use of antihypertensive agents to achieve BP control in patients with hypertension and aortic stenosis is beneficial. Although there are no specific trials comparing various classes of antihypertensive agents, RAS blockade may be advantageous because of the potentially beneficial effects on LV fibrosis (3), control of hypertension, reduction of dyspnea, and improved effort tolerance (4). Diuretics should be used sparingly in patients with small LV chamber dimensions. Beta blockers may be appropriate for patients with aortic stenosis who have reduced ejection fraction, prior MI, arrhythmias, or angina pectoris. In patients with moderate or severe aortic stenosis, consultation or co-management with a cardiologist is preferred for hypertension management.

2. Vasodilator therapy can reduce the LV volume and mass and improve LV performance in patients with aortic regurgitation (5), but improvement of long-term clinical outcomes, such as time to valve replacement, have been variable (5, 6). Beta blockers may result in increased diastolic filling period because of bradycardia, potentially causing increased aortic insufficiency. Marked reduction in DBP may lower coronary perfusion pressure in patients with chronic severe aortic regurgitation (stage B [progressive asymptomatic aortic regurgitation] and stage C [asymptomatic severe AR]). However, there are no outcomes data to support these theoretical concerns.

Synopsis

Thoracic aortic aneurysms are generally asymptomatic until a person presents with a sudden catastrophic event, such as an aortic dissection or rupture, which is rapidly fatal in the majority of patients (3, 4). The rationale for antihypertensive therapy is based largely on animal and observational studies associating hypertension with aortic dissection (5, 6). RCTs specifically addressing hypertension and aortic disease are not available, and trials in patients with primary hypertension do not provide insight on either the optimal BP
target or choice of antihypertensive drug therapy in patients with thoracic aortic aneurysm, aortic dissection, or aortic disease (7, 8). A study in 20 humans with hypertension suggested that hypertension is associated with significant changes in the mechanical properties of the aortic wall, with more strain-induced stiffening in hypertension than in normotension, which may reflect destruction of elastin and predisposition to aortic dissection in the presence of hypertension (9). In a retrospective observational study, high BP variability was an independent risk factor for the prognosis of aortic dissection (10). Recommendations for treatment of acute aortic dissection are provided in Section 11.2.

Recommendation-Specific Supportive Text

1. In patients with chronic aortic dissection, observational studies suggest lower risk for operative repair with beta-blocker therapy (1). In a series of patients with type A and type B aortic dissections, beta blockers were associated with improved survival in both groups, whereas ACE inhibitors did not improve survival (2).

10. Special Patient Groups

Special attention is needed for specific patient subgroups.

10.1. Race and Ethnicity

In the United States, at any decade of life, blacks have a higher prevalence of hypertension than that of Hispanic Americans, whites, Native Americans, and other subgroups defined by race and ethnicity (see Section 3.3). Hypertension control rates are lower for blacks, Hispanic Americans, and Asian Americans than for whites (1). Among men with hypertension, non-Hispanic white (53.8%) adults had a higher prevalence of controlled high blood pressure than did non-Hispanic black (43.8%), non-Hispanic Asian (39.9%), and Hispanic (43.5%) adults. For women with hypertension, the percentage of non-Hispanic white (59.1%) adults with controlled
high blood pressure was higher than among non-Hispanic black (52.3%) and non-Hispanic Asian (46.8%) adults (1). In Hispanic Americans, the lower control rates result primarily from lack of awareness and treatment (2, 3), whereas in blacks, awareness and treatment are at least as high as in whites, but hypertension is more severe and some agents are less effective at BP control (4). Morbidity and mortality attributed to hypertension are also more common in blacks and Hispanic Americans than in Whites. Blacks have a 1.3-times greater risk of nonfatal stroke, 1.8-times greater risk of fatal strokes, 1.5-times greater risk of HF, and 4.2-times greater risk of ESRD (4). Hispanic Americans have lower rates of hypertension awareness and treatment than those of whites and blacks, as well as a high prevalence of comorbid CVD risk factors (e.g., obesity, DM). In 2014, age-adjusted hypertension-attributable mortality rates per 1,000 persons for non-Hispanic white, non-Hispanic black, and Hispanic-American men and women were 19.3 and 15.8, 50.1 and 35.6, and 19.1 and 14.6, respectively (5). However, Hispanics in the United States are a heterogeneous subgroup, and rates of both hypertension and its consequences vary according to whether their ancestry is from the Caribbean, Mexico, Central or South America, or Europe (6-8). Hispanics from Mexico and Central America have lower CVD rates than U.S. whites, whereas those of Caribbean origin have higher rates. Thus, pooling of data for Hispanics may not accurately reflect risk in a given patient. Finally, the excess risk of CKD outcomes in at least some blacks with hypertension may be due to the presence of high-risk APOL1 (apolipoprotein L1) genetic variants (9-11). The rate of renal decline associated with this genotype appears to be largely unresponsive to either BP lowering or RAS inhibition (9-12).

### Synopsis

Lifestyle modification (i.e., weight reduction, dietary modification, and increased physical activity) is particularly important in blacks and Hispanic Americans for prevention and first-line or adjunctive therapy of hypertension (see Sections 12.1.2 and 12.1.3). However, the adoption of lifestyle recommendations is often challenging in ethnic minority patients because of poor social support, limited access to exercise opportunities and healthy foods, and financial considerations. The greater prevalence of lower socioeconomic status may impede access to basic living necessities (8), including medical care and medications. Consideration must also be given to learning styles and preference, personal beliefs, values, and culture (9, 10).

The principles of antihypertensive drug selection discussed in Sections 8.1.4 through 8.1.6 apply to ethnic minorities with a few caveats. In Blacks, thiazide-type diuretics and CCBs are more effective in lowering BP when given as monotherapy or as initial agents in multidrug regimens (11-13). In addition, thiazide-type agents are superior to drugs that inhibit the RAS (i.e., ACE inhibitors, ARBs, renin inhibitors, and beta blockers) for prevention of selected clinical outcomes in blacks (2, 14-16). For optimum endpoint protection, the thiazide chlorthalidone should be administered at a dose of 12.5 to 25 mg/day (or 25–50 mg/d for hydrochlorothiazide) because lower doses are either unproven or less effective in clinical outcome trials (2, 16). The CCB amlodipine is as effective as chlorthalidone and more effective than the ACE inhibitor lisinopril in reducing BP, CVD, and stroke events but less effective in preventing HF. Blacks have a greater risk of angioedema with ACE inhibitors (2, 3), and Asian Americans have a higher incidence of ACE inhibitor–induced cough (17). ACE inhibitors and ARBs are recommended more generally as components of multidrug antihypertensive regimens in blacks with CKD (see Section 9.3), with the addition of beta blockers in those with HF (see Section 9.2). Beta blockers are recommended for treatment of patients with CHD who have had a MI. Most patients with hypertension, especially blacks, require ≥2 antihypertensive medications to achieve adequate BP control. A single-tablet combination that includes either a diuretic or a CCB may be particularly effective in achieving BP control in blacks. Racial and ethnic differences should not be the basis for excluding any class of antihypertensive agent in combination therapy.

### Recommendation-Specific Supportive Text

1. In blacks, thiazide diuretics or CCBs are more effective in lowering BP than are RAS inhibitors or beta blockers and more effective in reducing CVD events than are RAS inhibitors or alpha blockers. RAS inhibitors are recommended in black patients with hypertension, DM, and nephropathy, but they offer no advantage over diuretics or CCBs in hypertensive patients with DM without nephropathy or HF.

2. Four drug classes (thiazide diuretic, CCB, ACE inhibitor, or ARB) lower BP and reduce cardiovascular or renal outcomes (18-21). Thus, except for the combination of ACE inhibitors and ARBs, regimens containing a combination of these classes are reasonable to achieve the BP target (16, 21). Furthermore, the combination of an ACE inhibitor or ARB with a CCB or thiazide diuretic produces similar BP lowering in blacks as in other
racial or ethnic groups. For blacks who do not achieve control with 3 drugs, see resistant hypertension (see Section 11.1).

References
10.2. Sex-Related Issues

The prevalence of hypertension is lower in women than in men until about the fifth decade but is higher later in life (1). Other than special recommendations for management of hypertension during pregnancy, there is no evidence that the BP threshold for initiating drug treatment, the treatment target, the choice of initial antihypertensive medication, or the combination of medications for lowering BP differs for women versus men (2, 3).

References

10.2.1. Women

A potential limitation of RCTs, including SPRINT, is that they are not specifically powered to determine the value of intensive SBP reduction in subgroups, including women in the case of SPRINT. However, in prespecified analyses, there was no evidence of an interaction between sex and treatment effect. Furthermore, no significant differences in CVD outcomes were observed between men and women in a large meta-analysis that included 31 RCTs with about 100,000 men and 90,000 women with hypertension (1). Some have called for a SPRINT-like trial with sufficient power to assess the effects of intensive SBP reduction in women (2). In meta-analyses, there was no convincing evidence that different antihypertensive drug classes exerted sex-related differences in BP lowering or provided distinct CVD protection (1). Calcium antagonists offered slightly greater benefits for stroke prevention than did ACE inhibitors for women than for men, whereas calcium antagonists reduced all-cause deaths compared with placebo in men but not in women. However, these sex-related differences might have been due to chance because of the large number of statistical comparisons that were performed. The Heart Attack Trial and Hypertension Care Computing Project reported that beta blockers were associated with reduced mortality in men but not in women, but this finding was likely due to the low event rates in women (3). Similarly, in the open-label Second Australian National BP study, a significant reduction in CVD events was demonstrated in men but not in women with ACE inhibitors versus diuretics (4).

Adverse effects of antihypertensive therapy were noted twice as often in women as in men in the TOMHS study (5). A higher incidence of ACE inhibitor–induced cough and of edema with calcium antagonists was observed in women than in men (6). Women were more likely to experience hypokalemia and hyponatremia and less likely to experience gout with diuretics (7). Hypertension in pregnancy has special requirements (see Section 10.2.2).

| III: Harm | C-LD | 2. Women with hypertension who become pregnant should not be treated with ACE inhibitors, ARBs, or direct renin inhibitors (4-6). |

Synopsis

BP usually declines during the first trimester of pregnancy and then slowly rises. Hypertension management during pregnancy includes 4 general areas: 1) the newly pregnant mother with existing hypertension; 2) incident hypertension; 3) preeclampsia (a dangerous form of hypertension with proteinuria that has the potential to result in serious adverse consequences for the mother [stroke, HF] and fetus [small for gestational age, premature birth]); and 4) severe hypertension, often in the setting of preeclampsia, requiring urgent treatment to prevent HF, stroke, and adverse fetal outcomes. Hypertension during pregnancy and preeclampsia are recognized as risk factors for future hypertension and CVD (7-9). BP management during pregnancy is complicated by the fact that many commonly used antihypertensive agents, including ACE inhibitors and ARBs, are contraindicated during pregnancy because of potential harm to the fetus (2, 3). The goal of antihypertensive treatment during pregnancy includes prevention of severe hypertension and the possibility of prolonging gestation to allow the fetus more time to mature before delivery.

There are 3 Cochrane database reviews of treatment for mild-to-moderate hypertension during pregnancy (10-12). With regard to the treatment of mild-to-moderate hypertension (SBP of 140–169 or DBP of 90–109 mm Hg), antihypertensive treatment reduces the risk of progression to severe hypertension by 50% compared with placebo but has not been shown to prevent preeclampsia, preterm birth, small for gestational age, or infant mortality. Beta blockers and CCBs appear superior to alpha-methyldopa in preventing preeclampsia (10). An earlier review of 2 small trials did not show improved outcomes with more comprehensive treatment of BP to a target of <130/80 mm Hg (11). Consistent with the results of the Cochrane reviews, a large multinational RCT of treatment in pregnant women with mild-to-moderate hypertension also reported that treatment prevented progression to severe hypertension, but other maternal and infant outcomes were unaffected by the intensity of treatment (13). An earlier review confined to assessing the effect of beta blockers found them generally safe and effective but of no benefit for newborn outcomes, either in placebo-controlled studies or when compared with other antihypertensive agents. There was a suggestion that beta-blocker therapy might be associated with small for gestational age and neonatal bradycardia (12). The largest experience for beta blockers is with labetalol; the largest experience for CCBs is with nifedipine.
Methyldopa and hydralazine may also be used. A review of treatment for pregnancy-associated severe hypertension found insufficient evidence to recommend specific agents; rather, clinician experience was recommended in this setting (14).

Preeclampsia is a potentially dangerous condition for the pregnant woman and fetus, occurring in 3.8% of pregnancies, and preeclampsia and eclampsia account for 9% of maternal deaths in the United States (15). Preeclampsia is associated with an increased risk of preterm delivery, intrauterine growth restriction, placental abruption, and perinatal mortality and is twice as likely to occur in the first pregnancy. The U.S. Preventive Services Task Force has recommended screening all pregnant women for preeclampsia by measuring BP at every prenatal visit (16).

It is beyond the scope of the present guideline to address the management of hypertension during pregnancy in detail. Several international guidelines provide guidance on management of hypertension during pregnancy (2, 3, 17). The American College of Obstetricians and Gynecologists has issued a task force report that includes recommendations for prevention (aspirin in selected cases) and treatment (magnesium for severe hypertension) of hypertension in pregnancy (2). A report detailing treatment of hypertensive emergencies during pregnancy and postpartum has also been released (2, 17, 18).

**Recommendation-Specific Supportive Text**

1. ACE inhibitors and ARBs are not approved for use during pregnancy; they are fetotoxic. Among the agents recommended, no specific agent is first choice because there are no data supporting one over another. Therapeutic classes are not recommended because potential toxicity differs among agents within classes.

2. ACE inhibitors and ARBs are fetotoxic in the second and third trimesters of pregnancy. Adverse effects in the first trimester of pregnancy may be secondary to hypertension or the medication (4, 5). Adverse events in the later trimesters have been suggested by observational data and meta-analyses (6). For ARBs, case reports with effects similar to ACE inhibitors have been published (19).

**References**

10.3. Age-Related Issues

### 10.3.1. Older Persons

**Synopsis**

Because of its extremely high prevalence in older adults, hypertension is not only a leading cause of preventable morbidity and mortality but, perhaps more importantly, is under-recognized as a major contributor to premature disability and institutionalization (2-5). Both SBP and DBP increase linearly up to the fifth or sixth decade of life, after which DBP gradually decreases while SBP continues to rise (6). Thus, isolated systolic hypertension is the predominant form of hypertension in older persons (7, 8). RCTs have clearly demonstrated that BP lowering in isolated systolic hypertension (defined as SBP ≥160 mm Hg with variable DBP ≤90, ≤95, or ≤110 mm Hg) is effective in reducing the risk of fatal and nonfatal stroke (primary outcome), cardiovascular events, and death (9-12).

Cross-sectional and longitudinal epidemiologic studies in older adults have raised questions about the benefits of more intensive antihypertensive treatment and the relationship between BP lowering and risk of falls (13). Treatment of elevated BP in older persons is challenging because of a high degree of heterogeneity in comorbidity, as well as poly-pharmacy, frailty, cognitive impairment, and variable life expectancy. However, over the past 3 decades, RCTs of antihypertensive therapy have included large numbers of older persons, and in every instance, including when the SBP treatment goal was <120 mm Hg, more intensive treatment has...
safely reduced the risk of CVD for persons over the ages of 65, 75, and 80 years (1, 14). Both HYVET (Hypertension in the Very Elderly Trial) and SPRINT included those who were frail but still living independently in the community (1, 14), and both were stopped early for benefit (HYVET after 1.8 years and SPRINT after 3.26 years). In fact, BP-lowering therapy is one of the few interventions shown to reduce mortality risk in frail older individuals. RCTs in noninstitutionalized community-dwelling older persons have also demonstrated that improved BP control does not exacerbate orthostatic hypotension and has no adverse impact on risk of injurious falls (1, 15, 16). It should be noted, however, that SPRINT excluded those with low (<110 mm Hg) standing BP on study entry. Older persons need to be carefully monitored for orthostatic hypotension during treatment. Intensive BP control increases the risk of acute kidney injury, but this is no different from the risk seen in younger adults (1). In summary, despite the complexity of management in caring for older persons with hypertension, RCTs have demonstrated that in many community-dwelling older adults, even adults >80 years of age, BP-lowering goals during antihypertensive treatment need not differ from those selected for persons <65 years of age (17). Importantly, no randomized trial of BP lowering in persons >65 years of age has ever shown harm or less benefit for older versus younger adults. However, clinicians should implement careful titration of BP lowering and monitoring in persons with high comorbidity burden; large RCTs have excluded older persons at any age who live in nursing homes, as well as those with prevalent dementia and advanced HF.

Recommendation-Specific Supportive Text

1. We recommend ASCVD risk assessment in all adults with hypertension, including older persons. As a matter of convenience, however, it can be assumed that the vast majority of older adults have a 10-year ASCVD risk ≥ 10%, placing them in the high risk category that requires initiation of antihypertensive drug therapy at BP ≥ 130/80 mm Hg (see Section 8.1.2, Figure 4 and Table 23 for BP thresholds for initiating antihypertensive drug treatment). Large RCTs using medications to reduce hypertension-related CVD risk with a mean follow-up of ≥2 years have now included a large number of adults ≥65 years of age. These trials have enrolled a broad range of ages ≥65 years, including persons in their 90s and even 100s, as well as those with mild-to-moderate frailty but who were ambulatory and able to travel to a treatment clinic. In these patients, RCTs have shown that BP lowering decreased CVD morbidity and mortality but did not increase the risk of orthostatic hypotension or falls (1, 15, 16). Analysis of the NHANES (2011–2014) data set indicates that 88% of U.S. adults (98% men and 80% women) ≥65 years old have a 10-year predicted ASCVD risk ≥10% or have a history of CVD (CHD, stroke, or HF). For persons ≥75 years of age, 100% have an ASCVD risk score ≥10% or a history of CVD. Therefore, the BP target of ≤130/80 mm Hg would be appropriate (see Section 8.1.2). Initiation of antihypertensive therapy with 2 agents should be undertaken cautiously in older persons, and they need to be monitored carefully for orthostatic hypotension and history of falls. In SPRINT, the benefit was for an SBP goal of <120 mm Hg. Older persons may present with neurogenic orthostatic hypotension associated with supine hypertension. This is particularly common in Parkinson’s disease and other neurodegenerative disorders. For management of this problem, the reader is referred to the recommendations of a 2017 consensus panel (18).

2. Patients with prevalent and frequent falls, advanced cognitive impairment, and multiple comorbidities may be at risk of adverse outcomes with intensive BP lowering, especially when they require multiple BP-lowering medications. Older persons in this category typically reside in nursing homes and assisting living facilities, are unable to live independently in the community, and have not been represented in RCTs.

References

10.3.2. Children and Adolescents

Pediatric guidelines are available from other organizations (1, 2). The 2011 report updates the 2004 report for publications through 2008 (antihypertensive medication trials, normative data on pediatric BP) but is otherwise unchanged. In the 2011 guideline (3), BP was stratified into normal, prehypertension (90th percentile to 95th percentile), stage 1 hypertension (95th percentile to >99th percentile), and stage 2 hypertension (above stage 1) by using age-, sex-, and height-based tables beginning at 1 year of age, which were based on the distribution of BP in more than 60,000 healthy children in various population-based studies (1). These definitions were designed to be analogous to definitions in the extant JNC 7 report; for older adolescents (≥14 years), the JNC 7 thresholds generally apply (4). Treatment recommendations are based on hypertension severity, published short-term clinical trials of antihypertensive treatment, age, coexisting CVD risk factors, and risk stratification by presence of LVH on echocardiogram. The treatment goal is to achieve BP <90th percentile. New tables for ambulatory BP distribution in children have been developed. A classification of BP that is based on these ambulatory BP results has been proposed (5, 6). Publication of new evidence-based pediatric guidelines is anticipated in late 2017.
11. Other Considerations

11.1. Resistant Hypertension

The diagnosis of resistant hypertension is made when a patient takes 3 antihypertensive medications with complementary mechanisms of action (a diuretic should be 1 component) but does not achieve control or when BP control is achieved but requires ≥4 medications (1). On the basis of the previous cutoff of 140/90 mm Hg, the prevalence of resistant hypertension is approximately 13% in the adult population (2, 3). Multiple single-cohort studies have indicated that common risk factors for resistant hypertension include older age, obesity, CKD, black race, and DM. Estimates suggest the prevalence would be about 4% higher with the newly recommended control target of <130/80 mm Hg (subject to validation in future study). The prognosis of resistant hypertension (by the previous definition) (1), compared with the prognosis of those who more readily achieve control, has not been fully ascertained; however, risk of MI, stroke, ESRD, and death in adults with resistant hypertension and CHD may be 2- to 6-fold higher than in hypertensive adults without resistant hypertension (4-6). The evaluation of resistant hypertension involves consideration of many patient characteristics, pseudoresistance (BP technique, white coat hypertension, and medication compliance), and screening for secondary causes of hypertension (Figure 10; Section 5.4; Table 13). The term “refractory hypertension” has been used to refer to an extreme phenotype of antihypertensive treatment failure, defined as failure to control BP despite use of at least 5 antihypertensive agents of different classes, including a long-acting thiazide-type diuretic, such as chlorthalidone, and a mineralocorticoid receptor antagonist, such as spironolactone (7). The prevalence of refractory hypertension is low; patients with refractory hypertension experience high rates of CVD complications, including LVH, HF, and stroke.

Treatment of resistant hypertension involves improving medication adherence, improving detection and correction of secondary hypertension, and addressing other patient characteristics (8-10). Pharmacological therapy with combinations of medications with complementary mechanisms of action provides an empirical approach that enhances BP control while mitigating untoward effects of potent vasodilators (e.g., fluid retention and reflex tachycardia). CCBs, inhibitors of RAS, and chlorthalidone comprise a common 3-drug regimen (11). Considerable evidence indicates that the addition of spironolactone to multidrug regimens provides substantial BP reduction (12) when compared with placebo. Substantial data also demonstrate the advantage of spironolactone as compared with other active drugs (8, 13-15). In particular, the recent PATHWAY-2 (Optimum Treatment for Drug-Resistant Hypertension) RCT demonstrated the superiority of spironolactone over alpha and beta blockers (13). There is also clinical trial evidence that the addition of hydralazine or minoxidil is effective in achieving BP control in patients resistant to usual
combination therapy (8, 12-16). The dosing of multidrug regimens, occasionally including nighttime dosing, may be best optimized by hypertension specialists.

Several studies have investigated devices that interrupt sympathetic nerve activity (carotid baroreceptor pacing and catheter ablation of renal sympathetic nerves); however, these studies have not provided sufficient evidence to recommend the use of these devices in managing resistant hypertension (8-10). In particular, 2 RCTS of renal sympathetic nerve ablation have been negative (8, 9).

Primary aldosteronism (elevated aldosterone/renin ratio)
CKD (eGFR <60 mL/min/1.73 m²)
Renal artery stenosis (young female; known atherosclerotic disease; worsening kidney function)
Pheochromocytoma (episodic hypertension, palpitations, diaphoresis, headache)
Obstructive sleep apnea (snoring, witnessed apnea, excessive daytime sleepiness)

↓
Pharmacological treatment
Maximize diuretic therapy
Add a mineralocorticoid receptor antagonist
Add other agents with different mechanisms of actions
Use loop diuretics in patients with CKD
and/or patients receiving potent vasodilators (e.g., minoxidil)

↓
Refer to specialist
Refer to appropriate specialist for known or suspected secondary cause(s) of hypertension
Refer to hypertension specialist if BP remains uncontrolled after 6 mo of treatment

*See additional details in Section 6, Nonpharmacological Intervention.
†See Section 5.4.1 and Table 14 for complete list of drugs that elevate BP.
‡See Section 5.4 and Table 13 for secondary hypertension.

BP indicates blood pressure; CKD, chronic kidney disease; DBP, diastolic blood pressure; eGFR, estimated glomerular filtration rate; NSAIDs, nonsteroidal anti-inflammatory drugs; and SBP, systolic blood pressure.

Synopsis

Hypertensive emergencies are defined as severe elevations in BP (>180/120 mm Hg) associated with evidence of new or worsening target organ damage (3-6). The 1-year death rate associated with hypertensive emergencies is >79%, and the median survival is 10.4 months if the emergency is left untreated (7). The actual BP level may not be as important as the rate of BP rise; patients with chronic hypertension can often tolerate higher BP levels than previously normotensive individuals. Hypertensive emergencies demand immediate reduction of BP (not necessarily to normal) to prevent or limit further target organ damage. Examples of target organ damage include hypertensive encephalopathy, ICH, acute ischemic stroke, acute MI, acute LV failure with pulmonary edema, unstable angina pectoris, dissecting aortic aneurysm, acute renal failure, and eclampsia. In general, use of oral therapy is discouraged for hypertensive emergencies. Hypertensive emergencies in patients with acute ICH and acute ischemic stroke are discussed in Section 9.4.

In contrast, hypertensive urgencies are situations associated with severe BP elevation in otherwise stable patients without acute or impending change in target organ damage or dysfunction. Many of these patients have withdrawn from or are noncompliant with antihypertensive therapy and do not have clinical or laboratory evidence of acute target organ damage. These patients should not be considered as having a hypertensive emergency and instead are treated by reinstatement or intensification of antihypertensive drug therapy and treatment of anxiety as applicable. There is no indication for referral to the emergency department, immediate reduction in BP in the emergency department, or hospitalization for such patients.

Figure 11 is an algorithm on diagnosis and management of a hypertensive crisis. Tables 19 and 20 summarize intravenous antihypertensive drugs for treatment of hypertensive emergencies.

Recommendation-Specific Supportive Text

1. There is no RCT evidence that antihypertensive drugs reduce morbidity or mortality in patients with hypertensive emergencies (8). However, from clinical experience, it is highly likely that antihypertensive therapy is an overall benefit in a hypertensive emergency (9). There is also no high-quality RCT evidence to inform clinicians as to which first-line antihypertensive drug class provides more benefit than harm in hypertensive emergencies (8). This lack of evidence is related to the small size of trials, the lack of long-term follow-up, and failure to report outcomes. However, 2 trials have demonstrated that nicardipine may be better than labetalol in achieving the short-term BP target (1, 10-12). Several antihypertensive agents in various pharmacological classes are available for the treatment of hypertensive emergencies (Table 19). Because
autoregulation of tissue perfusion is disturbed in hypertensive emergencies, continuous infusion of short-acting titratable antihypertensive agents is often preferable to prevent further target organ damage (5, 6). The selection of an antihypertensive agent should be based on the drug’s pharmacology, pathophysiological factors underlying the patient’s hypertension (as well as they can be rapidly determined), degree of progression of target organ damage, the desirable rate of BP decline, and the presence of comorbidities (Table 20). The therapeutic goal is to minimize target organ damage safely by rapid recognition of the problem and early initiation of appropriate antihypertensive treatment.

2. Compelling conditions requiring rapid lowering of SBP, usually to <140 mm Hg, in the first hour of treatment include aortic dissection, severe preeclampsia or eclampsia, and pheochromocytoma with hypertensive crisis.

3. There is no RCT evidence comparing different strategies to reduce BP, except in patients with ICH (9, 13). Neither is there RCT evidence to suggest how rapidly or how much BP should be lowered in a hypertensive emergency (9). However, clinical experience indicates that excessive reduction of BP may cause or contribute to renal, cerebral, or coronary ischemia and should be avoided. Thus, comprehensive dosing of intravenous or even oral antihypertensive agents to rapidly lower BP is not without risk. Oral loading doses of antihypertensive agents can engender cumulative effects, causing hypotension after discharge from the emergency department or clinic.
Figure 11. Diagnosis and Management of a Hypertensive Crisis

SBP >180 mm Hg and/or DBP >120 mm Hg

Target organ damage new/progressive/worsening

<thead>
<tr>
<th>Class</th>
<th>Drug(s)</th>
<th>Usual Dose Range</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>CCB—dihydropyridines</td>
<td>Nicardipine</td>
<td>Initial 5 mg/h, increasing every 5 min by 2.5 mg/h to maximum 15 mg/h.</td>
<td>Contraindicated in advanced aortic stenosis; no dose adjustment needed for elderly.</td>
</tr>
<tr>
<td></td>
<td>Clevidipine</td>
<td>Initial 1–2 mg/h, doubling every 90 s until BP approaches target, then increasing by less than double every 5–10 min; maximum dose 32 mg/h; maximum duration 72 h.</td>
<td>Contraindicated in patients with soybean, soy product, egg, and egg product allergy and in patients with defective lipid metabolism (e.g., pathological hyperlipidemia, lipoid nephrosis or acute pancreatitis). Use low-end dose range for elderly patients.</td>
</tr>
<tr>
<td>Vasodilators—Nitric-oxide dependent</td>
<td>Sodium nitroprusside</td>
<td>Initial 0.3–0.5 mcg/kg/min; increase in increments of 0.5 mcg/kg/min to achieve BP target; maximum dose 10 mcg/kg/min; duration of treatment as short as possible. For infusion rates ≥4–10 mcg/kg/min or duration &gt;30 min, thiosulfate can be coadministered to prevent cyanide toxicity.</td>
<td>Intra-arterial BP monitoring recommended to prevent “overshoot.” Lower dosing adjustment required for elderly. Tachyphylaxis common with extended use. Cyanide toxicity with prolonged use can result in irreversible neurological changes and cardiac arrest.</td>
</tr>
<tr>
<td></td>
<td>Nitroglycerin</td>
<td>Initial 5 mcg/min; increase in increments of 5 mcg/min every 3–5 min to a maximum of 20 mcg/min.</td>
<td>Use only in patients with acute coronary syndrome and/or acute pulmonary edema. Do not use in volume-depleted patients.</td>
</tr>
<tr>
<td>Vasodilators—direct</td>
<td>Hydralazine</td>
<td>Initial 10 mg via slow IV infusion (maximum initial dose 20 mg); repeat every 4–6 h as needed.</td>
<td>BP begins to decrease within 10–30 min, and the fall lasts 2–4 h. Unpredictability of response and prolonged duration of action do not make hydralazine a desirable first-line agent for acute treatment in most patients.</td>
</tr>
<tr>
<td>Adrenergic blockers—beta1 receptor selective antagonist</td>
<td>Esmolol</td>
<td>Loading dose 500–1000 mcg/kg/min over 1 min followed by a 50-mcg/kg/min infusion. For additional dosing, the bolus dose is repeated and the infusion increased in 50-mcg/kg/min increments as needed to a maximum of 200 mcg/kg/min.</td>
<td>Contraindicated in patients with concurrent beta-blocker therapy, bradycardia, or decompensated HF. Monitor for bradycardia. May worsen HF. Higher doses may block beta2 receptors and impact lung function in reactive airway disease.</td>
</tr>
<tr>
<td>Adrenergic blockers—combined alpha1 and nonselective</td>
<td>Labetalol</td>
<td>Initial 0.3–1.0-mg/kg dose (maximum 20 mg) slow IV injection every 10 min or 0.4–1.0-mg/kg/h IV infusion up to 3 mg/kg/h. Adjust</td>
<td>Contraindicated in reactive airways disease or chronic obstructive pulmonary disease. Especially useful in hyperadrenergic syndromes. May worsen HF and should not be given in</td>
</tr>
<tr>
<td>Beta receptor antagonist</td>
<td>Rate up to total cumulative dose of 300 mg. This dose can be repeated every 4–6 h.</td>
<td>Patients with second- or third-degree heart block or bradycardia.</td>
<td></td>
</tr>
<tr>
<td>-------------------------</td>
<td>---------------------------------------------------------------------------------</td>
<td>------------------------------------------------------------------</td>
<td></td>
</tr>
<tr>
<td>Adrenergic blockers—nonselective alpha receptor antagonist</td>
<td>Phentolamine IV bolus dose 5 mg. Additional bolus doses every 10 min as needed to lower BP to target.</td>
<td>Used in hypertensive emergencies induced by catecholamine excess (pheochromocytoma, interactions between monamine oxidase inhibitors and other drugs or food, cocaine toxicity, amphetamine overdose, or clonidine withdrawal).</td>
<td></td>
</tr>
<tr>
<td>Dopamine1-receptor selective agonist</td>
<td>Fenoldopam Initial 0.1–0.3 mcg/kg/min; may be increased in increments of 0.05–0.1 mcg/kg/min every 15 min until target BP is reached. Maximum infusion rate 1.6 mcg/kg/min.</td>
<td>Contraindicated in patients at risk of increased intraocular pressure (glaucoma) or intracranial pressure and those with sulfite allergy.</td>
<td></td>
</tr>
<tr>
<td>ACE inhibitor</td>
<td>Enalaprilat Initial 1.25 mg over a 5-min period. Doses can be increased up to 5 mg every 6 h as needed to achieve BP target.</td>
<td>Contraindicated in pregnancy and should not be used in acute MI or bilateral renal artery stenosis. Mainly useful in hypertensive emergencies associated with high plasma renin activity. Dose not easily adjusted. Relatively slow onset of action (15 min) and unpredictability of BP response.</td>
<td></td>
</tr>

<table>
<thead>
<tr>
<th>COR</th>
<th>LOE</th>
<th>Recommendation</th>
</tr>
</thead>
<tbody>
<tr>
<td>IIa</td>
<td>B-R</td>
<td>1. In adults with hypertension, BP lowering is reasonable to prevent cognitive decline and dementia (1-6).</td>
</tr>
</tbody>
</table>

**Synopsis**

Dementia is a leading cause of mortality and placement into nursing homes and assisted living facilities, affecting >46 million individuals globally and 5 million persons in the United States, a number that is expected to double by 2050 (7). A 5-year delay in onset of dementia would likely decrease the number of cases of incident dementia by about 50% after several decades (8). Vascular disease and its risk factors are implicated in a large proportion of patients with dementia, including those with Alzheimer’s dementia (9-11). Hypertension is also the primary risk factor for small-vessel ischemic disease and cortical white matter abnormalities (12-15). Most observational studies have suggested that better control of SBP may reduce Alzheimer’s disease and other dementias, and the evidence is stronger for BP lowering in middle age than in the elderly (9, 16). Clinical trials with dementia assessment have evaluated all-cause dementia but not Alzheimer’s disease specifically. However, all of these trials have methodological issues, such as low power, insufficient follow-up length, and inadequately designed dementia assessment batteries.

**Recommendation-Specific Supportive Text**

1. Five clinical trials of BP lowering have included assessment for incident dementia. Of these 5 trials, 4 demonstrated a reduction in dementia incidence, with 2 of these 4 demonstrating statistical significance (746-751). SYST-EUR (Systolic Hypertension in Europe) (17) and PROGRESS (Perindopril Protection Against Recurrent Stroke) (18) both showed statistically significant reductions in incident dementia. SYST-EUR achieved an SBP of 152 mm Hg in the treatment arm (8.3 mm Hg lower than placebo arm) during its blinded phase and an SBP of 149 mm Hg (7.0 mm Hg lower than comparison group) during its open-label follow-up phase (2, 3). PROGRESS achieved an SBP of 138 mm Hg in the treatment group (9 mm Hg lower than the placebo group) and demonstrated dementia prevention in patients with a recent stroke (5). The trial showing
no benefit in the direction of dementia reduction achieved an SBP reduction of only 3.2 mm Hg, whereas the other 4 trials achieved SBP reductions of 7 to 15 mm Hg (746-751). When the rate of cognitive decline (not dementia) has been a trial outcome, 7 clinical trials of BP-lowering therapy have been completed, and 2 of these have shown benefit (4-6, 19-22). No randomized trial of BP lowering has demonstrated an adverse impact on dementia incidence or cognitive function. However, the anticipated results from SPRINT, the first adequately powered RCT to test whether intensive BP control reduces dementia, may help clarify this issue in the near future.

11.4. Sexual Dysfunction and Hypertension

An association among sexual dysfunction, atherosclerosis, and hypertension can be constructed from several epidemiology surveys, clinical trials, and cohort studies. Although these data converge to suggest that endothelial dysfunction is a common denominator, the story is complete. Sexual dysfunction represents several domains in desire or interest, as well as physical limitations such as erectile dysfunction. In addition, beta blockers, mineralocorticoid receptor antagonists, and other antihypertensive drugs can have negative effects on libido and erectile function. There are emerging data on the association between erectile dysfunction and CVD compared with other domains of sexual dysfunction. Experimental and clinical studies describe a role for angiotensin II, endothelin, and hydrogen sulfide on cavernous tissue function (1). Many of the signaling pathways for the increased production of oxidative stress and the subsequent deleterious effects of oxidative stress on vascular tissue have been described. Accordingly, it is reasonable to suggest that hypertension might lead to vascular changes that cause erectile dysfunction but, conversely, erectile dysfunction may be part of the causal pathway to CVD (1). Although there is insufficient evidence to recommend screening for CVD risk factors in all men with erectile dysfunction, it has been reported as a sole precursor for CVD in men (2-6).

With the introduction of the phosphodiesterase-5 inhibitors, which can be coadministered with antihypertensive medications, there is now effective therapy for erectile dysfunction that has implications for systemic vascular disease (7). These drugs have additive effects on lowering BP and are recommended as a primary therapy for pulmonary hypertension (8). Although data are available to suggest that some antihypertensive medications affect erectile dysfunction more than others, the use of phosphodiesterase-5 inhibitors make drug class distinctions for erectile dysfunction less relevant (9). The long-term safety and efficacy of chronic administration of phosphodiesterase-5 inhibitors for the mitigation of CVD has yet to be determined and represents an important knowledge gap.

| Preoperative |
| I | B-NR | 1. In patients with hypertension undergoing major surgery who have been on beta blockers chronically, beta blockers should be continued (1-7). |
| IIa | C-E0 | 2. In patients with hypertension undergoing planned elective major surgery, it is reasonable to continue medical therapy for hypertension until surgery. |
| IIb | B-NR | 3. In patients with hypertension undergoing major surgery, discontinuation of ACE inhibitors or ARBs perioperatively may be considered (8-10). |
| IIb | C-LD | 4. In patients with planned elective major surgery and SBP of 180 mm Hg or higher or DBP of 110 mm Hg or higher, deferring surgery may be considered (11, 12). |
| III: Harm | B-NR | 5. For patients undergoing surgery, abrupt preoperative discontinuation of beta blockers or clonidine is potentially harmful (2, 13). |
| III: Harm | B-NR | 6. Beta blockers should not be started on the day of surgery in beta blocker–naive patients (14). |
| Intraoperative |
| I | C-E0 | 7. Patients with intraoperative hypertension should be managed with intravenous medications (Table 19) until such time as oral medications can be resumed. |

Synopsis

Hypertension in the perioperative period increases the risk of CVD, cerebrovascular events, and bleeding (15, 16). As many as 25% of patients who undergo major noncardiac surgery (17) and 80% of patients who have cardiac surgery experience perioperative hypertension (16, 18). In general, the level of risk is related to the severity of the hypertension.

No high-quality RCTs were identified relating to the treatment of hypertension in patients undergoing major surgical procedures. One analysis evaluated data from 3 prospective, randomized, open-label, parallel-comparison studies in patients undergoing cardiac surgery and concluded that clevidipine is a safe and effective treatment for acute hypertension in patients undergoing cardiac surgery (19). Another systematic review and meta-analysis, including 4 studies, concluded that clevidipine is more effective than other antihypertensive drugs in the management of perioperative hypertension without adverse events (20). Several general strategies and principles based on experience and observation are recommended for this section. In the management of patients with perioperative hypertension, it is important to assess other potential contributing factors, such as volume status, pain control, oxygenation, and bladder distention, when the use of pharmacological therapy to control BP is under consideration. Uncontrolled hypertension is associated with increased perioperative and postoperative complications. Certain medications (e.g., beta blockers, clonidine) may be associated with rebound hypertension if discontinued abruptly (13). Therefore,
several general strategies and principles based on experience and observation are recommended for this section.

These recommendations for beta blockers, ACE inhibitors, and ARBs are generally consistent with the “2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery” and are provided to assist in the management of patients undergoing major noncardiac surgical procedures (21).

**Recommendation-Specific Supportive Text**

1. If well tolerated, beta blockers should be continued in patients who are currently receiving them for longitudinal reasons, particularly when longitudinal treatment is provided according to GDMT, such as for MI (22). Multiple observational studies support the benefits of continuing beta blockers in patients who are undergoing surgery and who are on these agents for longitudinal indications (1-7).

2. In the absence of conclusive RCTs, the expert opinion of this writing committee is that control of BP to levels recommended by the present guideline (BP <130/80 mm Hg) or other target levels specified for a particular individual is reasonable before undertaking major elective procedures in either the inpatient or outpatient setting. If the patient is unable to take oral medications, it is reasonable to use intravenous medications (Table 19) as necessary to control BP. Special consideration of placement on parenteral therapy usually occurs for patients taking clonidine or beta blockers because of the risk of stopping these medications acutely. Withdrawal syndromes, accompanied by sympathetic discharge and acute hypertension, can occur on cessation of these agents (13).

3. Data on the potential risk and benefit of ACE inhibitors in the perioperative setting are limited to observational analyses, and this area is controversial. Recent evidence from a large cohort study demonstrates that patients who stopped their ACE inhibitors or ARBs 24 hours before noncardiac surgery were less likely to suffer the primary composite outcome (all-cause death, stroke, or myocardial injury) and intraoperative hypotension than were those continuing these medications until surgery (10).

4. JNC 6 (23) noted conflicting evidence for patients with DBP >110 mm Hg and recommended delay of surgery for gradual reduction in DBP before proceeding with surgery. In a systematic review and meta-analysis of 30 observational studies, preoperative hypertension was associated with a 35% increase in cardiovascular complications (12). An increased risk of complications, including dysrhythmias, myocardial ischemia or infarction, neurological complications, and renal failure, has been reported in patients with DBP ≥110 mm Hg immediately before surgery (24). In contrast, patients with DBP <110 mm Hg do not appear to be at significantly increased risk (25). The relationship of systolic hypertension to surgical risk is less certain. Among patients undergoing carotid endarterectomy, increased risk of postoperative hypertension and neurological defects were observed (26), and an increased risk of CVD morbidity after coronary artery bypass graft surgery has been observed in patients with isolated systolic hypertension (27). During induction of anesthesia for surgery, sympathetic action can result in a 20– to 30–mm Hg increase in BP and a 15- to 20-bpm increase in heart rate among patients with normal BP (24). Exaggerated responses may occur in patients with poorly treated or untreated hypertension by as much as 90 mm Hg and 40 bpm (24). With further anesthesia, the accompanying inhibition of the sympathetic nervous system and loss of baroreceptor control may result in intraoperative hypotension. Lability in BP appears more likely in patients with poorly controlled hypertension (25), whereas studies have observed that patients with controlled hypertension respond similarly to those who are normotensive (28). Early work indicated that patients with severe hypertension (SBP >210 mm Hg and DBP >105 mm Hg) had exaggerated responses in BP during the induction of anesthesia (28).

5. Although few studies describe risks of withdrawing beta blockers in the perioperative time period (2, 5), longstanding evidence from other settings suggests that abrupt withdrawal of long-term beta blockers is
harmful (29-31). There are fewer data to describe whether short-term (1 to 2 days) perioperative use of beta blockers, followed by rapid discontinuation, is harmful (5, 14, 21, 30).

6. The 2014 ACC/AHA perioperative guideline specifically recommends against starting beta blockers on the day of surgery in beta-blocker–naive patients (5, 21, 30), particularly at high initial doses, in long-acting form, and if there are no plans for dose titration or monitoring for adverse events. Data from the POISE (Perioperative Ischemic Evaluation) study demonstrate the risk of initiating long-acting beta blockers on the day of surgery (14).

7. Several antihypertensive agents in a variety of pharmacological classes are available for the treatment of hypertensive emergencies (Table 19).

12. Strategies to Improve Hypertension Treatment and Control

In addition to promoting pharmacological and nonpharmacological treatment adherence in individual patients with hypertension, several population-based systems approaches can play an important role in treatment goals.

12.1. Adherence Strategies for Treatment of Hypertension

Therapeutic nonadherence (not following recommended medical or health advice, including failure to “persist” with medications and recommended lifestyle modifications) is a major contributor to poor control of hypertension and a key barrier to reducing CVD deaths. Adherence rates vary substantially in different populations and, in general, are lower for lifestyle change and more behaviorally demanding regimens.
12.1.1. Antihypertensive Medication Adherence Strategies

| Recommendations for Antihypertensive Medication Adherence Strategies |
|----------------------|-----------------------------|
| References that support recommendations are summarized in Online Data Supplements 59 and 60. |

</tr>
<tr>
<td>IIA</td>
<td>B-NR</td>
<td>2. Use of combination pills rather than free individual components can be useful to improve adherence to antihypertensive therapy (4-7).</td>
</tr>
</tbody>
</table>

Synopsis

Up to 25% of patients do not fill their initial prescription for antihypertensive therapy (8-10). During the first year of treatment, the average patient has possession of antihypertensive medications only 50% of the time, and only 1 in 5 patients has sufficiently high adherence to achieve the benefits observed in clinical trials (11, 12).

Factors contributing to poor adherence are myriad, complex, and multilevel (11, 13, 14). Therefore, solutions to improve adherence may be introduced at patient, provider, and healthcare system levels (13, 15, 16). Several systematic reviews and meta-analyses have assessed the impact of interventions on adherence to antihypertensive medications, including modification of antihypertensive therapy (1-7, 11, 15, 16). No single intervention is uniquely effective, and a sustained, coordinated effort that targets all barriers to adherence in an individual is likely to be the most effective approach. See Online Data Supplement F for barriers to medication adherence and the most successful interventions.

The creation of an encouraging, blame-free environment in which patients are recognized for achieving treatment goals and given “permission” to answer questions related to their treatment honestly is essential to identify and address nonadherence. Patient medication adherence assessment tools (17) are presented in Online Data Supplement A. Members of the hypertension care team may use these self-report tools in a nonthreatening fashion to identify barriers and facilitate behaviors associated with improved adherence to antihypertensive medications. Use of more objective methods (e.g., pill counts, data on medication refills) to assess adherence along with self-report methods is optimal.

Recommendation-Specific Supportive Text

1. Remembering to take medication is often challenging, particularly for regimens that must be dosed several times daily. Taking medications several times throughout the day requires greater attention to scheduling, as well as additional issues such as transportation or storage, which can be challenging for some patients. The impact of once-daily dosing of antihypertensive drugs versus dosing multiple times daily has been evaluated in several meta-analyses (1-3). Medication adherence was greatest with once-daily dosing (range 71% to 94%) and declined as dosing frequency increased (1, 2).

2. Assessment and possible modification of drug therapy regimens can improve suboptimal adherence. Simplifying medication regimens, either by less frequent dosing (i.e., once daily versus multiple times daily) or use of combination drug therapy, improves adherence. Available fixed-dose combination drug therapy is listed in Online Data Supplement D.

### 12.1.2. Strategies to Promote Lifestyle Modification

<table>
<thead>
<tr>
<th>Recommendations</th>
<th>COR</th>
<th>LOE</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Effective behavioral and motivational strategies to achieve a healthy lifestyle (i.e., tobacco cessation, weight loss, moderation in alcohol intake, increased physical activity, reduced sodium intake, and consumption of a healthy diet) are recommended for adults with hypertension (1, 2).</td>
<td>I</td>
<td>C-EO</td>
</tr>
</tbody>
</table>

**Synopsis**

The primary lifestyle modification interventions that can help reduce high BP are outlined in Section 6 (healthy diet, weight loss, exercise and moderate alcohol intake). In addition, tobacco cessation is crucial for CVD risk reduction. These modifications are central to good health and require specific motivational and cognitive intervention strategies designed to promote adherence to these healthy behaviors. High-quality evidence supporting some of these strategies is provided in Online Data Supplement 6. Additionally, interventions such as goal setting, provision of feedback, self-monitoring, follow-up, motivational interviewing, and promotion of self-sufficiency are most effective when combined. Most individuals have clear expectations about what a
new lifestyle will provide; if their experiences do not match these expectations, they will be dissatisfied and less motivated to maintain a lifestyle change, particularly in environments that do not support healthy choices. Other factors that may influence adoption and maintenance of new physical activity or dietary behaviors include age, sex, baseline health status, and body mass index, as well as the presence of comorbid conditions and depression, which negatively affect adherence to most lifestyle change regimens (1). Primary strategies include cognitive-behavioral strategies for promoting behavior change, intervention processes and delivery strategies, and addressing cultural and social context variables that influence behavioral change.

Recommendation-Specific Supportive Text

1. It is crucial to translate and implement into practice the most effective evidence-based strategies for adherence to nonpharmacological treatment for hypertension. Both adoption and maintenance of new CVD risk-reducing behaviors pose challenges for many individuals. Success requires consideration of race, ethnicity, and socioeconomic status, as well as individual, provider, and environmental factors that may influence the design of such interventions (1). High-quality evidence has shown that even modest sustained lifestyle changes can substantially reduce CVD morbidity and mortality (1). Because many beneficial effects of lifestyle changes accrue over time, long-term adherence maximizes individual and population benefits. Interventions targeting sodium restriction, other dietary patterns, weight reduction, and new physical activity habits often result in impressive rates of initial behavior changes but frequently are not translated into long-term behavioral maintenance.

12.1.3. Improving Quality of Care for Resource-Constrained Populations

The availability of financial, informational, and instrumental support resources can be important though not sole determinants of hypertension control (1, 2). The management of hypertension in resource-constrained populations poses a challenge that will require the implementation of all recommendations discussed in Section 13 (Table 21), with specific sensitivity to challenges posed by limited financial resources, including those related to health literacy, alignment of and potential need to realign healthcare priorities by patients, the convenience and complexity of the management strategy, accessibility to health care, and health-related costs (including medications). Resource-constrained populations are also populations with high representation of groups most likely to manifest health disparities, including racial and ethnic minorities (see Section 10.1), residents located in rural areas, and older adults. The more comprehensive BP targets proposed in the present guideline will present added challenges in these populations.

It is crucial to invest in measures to enhance health literacy and reinforce the importance of adhering to treatment strategies, while paying attention to cultural sensitivities. These measures may include identification of and partnering with community resources and organizations devoted to hypertension control and cardiovascular health. Although comparative-effectiveness data documenting efficacy of various interventions are limited, multidisciplinary team–based approaches and the use of community health workers (see Sections 12.1.1 and 12.2) have shown some utility, as has the use of out-of-office BP monitoring (or no-cost BP control visits), particularly among resource-constrained populations (3-5). Long-acting once-daily medications (e.g., chlorthalidone, amlodipine) that are now available generically and often on discount formularies can often be used to reduce complexity of the regimen and promote adherence by decreasing the effect of missed medication dosages. When possible, prescriptions requiring longer than 30-day refills should
be considered, especially once a stable regimen is achieved. Where appropriate, using scored tablets and pill cutters can decrease the cost of medication for patients.

<td>1. A team-based care approach is recommended for adults with hypertension (1-7).</td>
</tr>
</tbody>
</table>

Synopsis

Team-based care to improve BP control is a health systems–level, organizational intervention that incorporates a multidisciplinary team to improve the quality of hypertension care for patients (8-10). Various team-based hypertension care models have been demonstrated to increase the proportion of individuals with controlled BP and to reduce both SBP and DBP (1-7, 11, 12). A team-based care approach is patient centered and is frequently implemented as part of a multifaceted approach, with systems support for clinical decision making (i.e., treatment algorithms), collaboration, adherence to prescribed regimen, BP monitoring, and patient self-management. Team-based care for hypertension includes the patient, the patient’s primary care provider, and other professionals, such as cardiologists, nurses, pharmacists, physician assistants, dietitians, social workers, and community health workers. These professionals complement the activities of the primary care provider by providing process support and sharing the responsibilities of hypertension care. Section 13 contains a comprehensive, patient-centered plan of care that should be the basis of all team-based care for hypertension.

Team-based care aims to achieve effective control of hypertension by application of the strategies outlined in Online Data Supplement H (3). Delineation of individual team member roles on the basis of knowledge, skill set, and availability, as well as the patient’s needs, allows the primary care provider to delegate routine matters to the team, thereby permitting more time to manage complex and critical patient-care issues. Important implementation aspects, such as type of team member added, role of team members related to medication management, and number of team members, influence BP outcomes (3, 13). Team member roles should be clear to all team members and to patients and families.

Team-based care often requires organizational change and reallocation of resources (14, 15). Systems-level support, such as use of electronic health records (EHR) (see Section 12.3.1), clinical decision support (i.e., treatment algorithms), technology-based remote monitoring (see Section 12.3.2), self-management support tools, and monitoring of performance, are likely to augment and intensify team-based care efforts to reduce high BP.
Recommendation-Specific Supportive Text

1. RCTs and meta-analyses of RCTs of team-based hypertension care involving nurse or pharmacist intervention demonstrated reductions in SBP and DBP and/or greater achievement of BP goals when compared with usual care (1, 2, 4, 5). Similarly, systematic reviews of team-based care, including a review of studies that included community health workers, for patients with primary hypertension showed reductions in SBP and DBP and improvements in BP control, appointment keeping, and hypertension medication adherence as compared with usual care (3, 12).

<tr>
<td>I</td>
<td>B-NR</td>
<td>2. Use of the EHR and patient registries is beneficial for guiding quality improvement efforts designed to improve hypertension control (1-3).</td>
</tr>
</tbody>
</table>

**Synopsis**

A growing number of health systems are developing or using registries and EHR that permit large-scale queries to support population health management strategies to identify undiagnosed or undertreated hypertension. Such innovations are implemented as ongoing quality improvement initiatives in clinical practice. To reduce undiagnosed hypertension and improve hypertension management, a multipronged approach may include 1) application of hypertension screening algorithms to EHR databases to identify at-risk patients, 2) contacting at-risk patients to schedule BP measurements, 3) monthly written feedback to clinicians about at-risk patients who have yet to complete a BP measurement, and 4) electronic prompts for BP measurements whenever at-risk patients visit the clinic (1, 2).

**Recommendation-Specific Supportive Text**

1. A growing number of health systems have implemented secure EHR and are developing databases that permit large-scale queries to support population health management strategies for more effective and accurate identification of patients with hypertension (1-3).

2. A growing number of health systems have implemented secure EHR and are developing databases that permit large-scale quality improvement initiative–designed queries to support population health management strategies for more effective management and control of hypertension (1-3).

12.3.2. Telehealth Interventions to Improve Hypertension Control

### Recommendation for Telehealth Interventions to Improve Hypertension Control

<table>
<thead>
<tr>
<th>COR</th>
<th>LOE</th>
<th>Recommendations</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ila</td>
<td>A</td>
<td>1. Telehealth strategies can be useful adjuncts to interventions shown to reduce BP for adults with hypertension (1-5).</td>
</tr>
</tbody>
</table>

**References**

Synopsis

Telehealth strategies, such as telemedicine, digital health (“eHealth”), and use of mobile computing and communication technologies (“mHealth”), are new and innovative tools to facilitate improvements in managing patients with hypertension. mHealth interventions show promise in reducing SBP in patients with hypertension but with large variability in behavioral targets, intervention components, delivery modalities, and patient engagement (5). In addition, there are important implications for the role of social networks, social media, and electronic technology as viable components of weight management and other lifestyle modification and disease management programs (6).

Commonly used telehealth interventions for hypertension management are listed in Online Data Supplement I. Wireless technologies (Online Data Supplement I) allow linking BP devices and other measurement devices to telephone- or Internet-based transmission systems or to Wi-Fi access points available in users’ homes and in communities. Some systems require patients to manually enter data, which is then forwarded to a remote computer or the mobile device of the telehealth provider through a telephone line or the Internet (7). When data are received, they are stored and analyzed, and reports are generated, including variations and averages in BP and other parameters over the recording period.

Recommendation-Specific Supportive Text

1. Meta-analyses of RCTs of different telehealth interventions have demonstrated greater SBP and DBP reductions (1, 2, 4) and a larger proportion of patients achieving BP control (2) than those achieved with usual care without telehealth. The effect of various telehealth interventions on BP lowering was significantly greater than that of BP self-monitoring without transmission of BP data, which suggests a possible added value of the teletransmission approach (1, 3). Although mHealth interventions in general showed promise in reducing SBP in patients with hypertension, results were inconsistent (5). It is unclear which combination of telehealth intervention features is most effective, and telehealth has not been demonstrated to be effective as a standalone strategy for improving hypertension control.

12.4.1. Performance Measures

<table>
<thead>
<tr>
<th>COR</th>
<th>LOE</th>
<th>Recommendation for Performance Measures</th>
</tr>
</thead>
<tbody>
<tr>
<td>IIa</td>
<td>B-NR</td>
<td>1. Use of performance measures in combination with other quality improvement strategies at patient-, provider-, and system-based levels is reasonable to facilitate optimal hypertension control (1-3).</td>
</tr>
</tbody>
</table>

Synopsis

Efforts to improve suboptimal medical care include the use of performance measures, which are defined as standardized, validated approaches to assess whether correct healthcare processes are being performed and that desired patient outcomes are being achieved (4). Performance measures are often combined with other quality improvement strategies, such as certification or financial incentives tied to higher-quality care (5). Guidelines help define clinical care standards that can be used to develop performance measures. As guidelines evolve over time to incorporate new evidence, related performance measures may also evolve.

Because identification, treatment, and control of hypertension are suboptimal, performance measures for hypertension control have been developed and recommended for use in quality improvement projects aimed at improving hypertension control and related outcomes in clinical practice (6-8). Because the specific methods used in performance measures can have an impact on their accuracy and ultimate impact (e.g., the method of BP measurement used in the assessment), they should be developed, tested, and implemented according to published standards (9). See Online Data Supplement J for publicly available performance measures to assess the quality of hypertension care (generally using JNC 7 criteria).

Recommendation-Specific Supportive Text

1. RCTs on the impact of performance measures on hypertension control are lacking; RCTs of quality improvement protocols have shown improvements in hypertension control (1, 2). Furthermore, a large observational study showed that a systematic approach to hypertension control, including the use of performance measures, was associated with significant improvement in hypertension control compared with historical control groups (3).

<tbody>
<tr>
<td>IIa</td>
<td>B-R</td>
<td>1. Use of quality improvement strategies at the health system, provider, and patient levels to improve identification and control of hypertension can be effective (1-8).</td>
</tr>
</tbody>
</table>

Synopsis

High-quality BP management is multifactorial and requires the engagement of patients, families, providers, and healthcare delivery systems (9). The difference between patient outcomes achieved with current hypertension treatment methods and patient outcomes thought to be possible with best-practice treatment methods is known as a quality gap, and such gaps are at least partly responsible for the loss of thousands of lives each year (10). This includes expanding patient and healthcare provider awareness, appropriate lifestyle modifications, access to care, evidence-based treatment, a high level of medication adherence, and adequate follow-up (9). Quality improvement strategies or interventions aimed at reducing the quality gap for a group of patients who are representative of those encountered in routine practice have been effective in improving the hypertension care and outcomes across a wide variety of clinic and community settings (1-4, 6, 8, 10).

Hypertension quality improvement strategies, with examples of substrategies that have been demonstrated to reduce BP and improve BP, are provided in Online Data Supplement E. Because the effects of the different quality improvement strategies varied across trials, and most trials included >1 quality improvement strategy, it is not possible to discern which specific quality improvement strategies have the greatest effects. Team-based care (see Section 12.4) and an organized system of regular review, with antihypertensive drug therapy implemented via a stepped-care protocol, had a clinically significant effect on reducing SBP and DBP and improving BP control. The assessed strategies in Online Data Supplement E may be beneficial under some circumstances and in varying combinations (1-5). National initiatives such as Million Hearts Make Control Your Goal Blood Pressure Toolkit and Team Up Pressure Down provide quality improvement tools to support hypertension care in communities and clinical settings (11). For other national and regional initiatives to improve hypertension, see Online Data Supplement G.

Recommendation-Specific Supportive Text

1. Systematic review and meta-analyses of trials of quality improvement interventions at health system, provider, and patient levels have demonstrated greater SBP and DBP reductions and a larger proportion of patients achieving BP control than those observed with no intervention or usual care. Multicomponent and multilevel strategies at the local community and healthcare delivery system levels have been shown to improve BP control (6, 7).

<td>1. Financial incentives paid to providers can be useful in achieving improvements in treatment and management of patient populations with hypertension (1-3).</td>
</tr>
<tr>
<td>Ila</td>
<td>B-NR</td>
<td>2. Health system financing strategies (e.g., insurance coverage and copayment benefit design) can be useful in facilitating improved medication adherence and BP control in patients with hypertension (4).</td>
</tr>
</tbody>
</table>

Synopsis

With the evolution of the U.S. health system to reward “value over volume,” payment systems have focused on financial incentives to improve quality of care. Use of performance measures promulgated by national organizations, governmental payers, and commercial payers have fostered greater attention to control of high BP among healthcare providers and their patients. These performance measures have formed the basis for determining financial incentives for pay for performance initiatives, commercial insurer “pay-for-value” contracts, and the Medicare Shared Savings Programs developed by the Centers for Medicare & Medicaid Services Innovation for Accountable Care Organizations. In addition, the Centers for Medicare and Medicaid Services has developed The Million Hearts: Cardiovascular Disease Risk Reduction Model, which is an RCT designed to identify and test scalable models of care delivery that reduce CVD risk (5).

Greater attention is being paid to the influence of health insurance coverage and benefit designs focused on reducing patient copayments for antihypertensive medications.

Recommendation-Specific Supportive Text

1. Moderate-quality evidence with mixed results suggests that population-based payment incentive programs can play an important role in achieving better BP control (1-3).
2. Reduced copayments for health care, including for medications, and improved outcomes of hypertension care have been identified in several U.S. studies and in single studies in Finland, Israel, and Brazil (4). This is consistent with other evidence on how copayments reduce uptake of care and has implications for policymakers, particularly because the balance of evidence does not suggest that reducing medication copayments leads to an increase in overall healthcare expenditure.

<td>1. Every adult with hypertension should have a clear, detailed, and current evidence-based plan of care that ensures the achievement of treatment and self-management goals, encourages effective management of comorbid conditions, prompts timely follow-up with the healthcare team, and adheres to CVD GDMT (Table 22).</td>
</tr>
</tbody>
</table>

Synopsis
A specific plan of care for hypertension is essential and should reflect understanding of the modifiable and nonmodifiable determinants of health behaviors, including the social determinants of risk and outcomes. A clinician’s sequential flow chart for management of hypertension is presented in Table 21. Detailed evidence-based elements of the plan of care are listed in Table 22. The determinants will vary among demographic subgroups (see Section 10 for additional information).

Recommendation-Specific Supportive Text
1. Studies demonstrate that implementation of a plan of care for hypertension can lead to sustained reduction of BP and attainment of BP targets over several years (1). Meta-analysis of RCTs shows reductions in BP of patients with hypertension and achievement of BP goals at 6 months and 1 year when compared with usual care.

ABPM indicates ambulatory blood pressure monitoring; ASCVD, atherosclerotic cardiovascular disease; BP, blood pressure; and HBPM, home blood pressure monitoring.

13.1. Health Literacy

Communicating alternative behaviors that support self-management of healthy BP in addition to medication adherence is important. This should be done both verbally and in writing. Today, mobile phones have a recording option. For patients with mobile phones, the phone can be used to inform patients and family members of medical instructions after the doctor’s visit as an additional level of communication. Inclusion of a family member or friend that can help interpret and encourage self-management treatment goals is suggested when appropriate. Examples of needed communication for alternative behaviors include a specific regimen relating to physical activity; a specific sodium-reduced meal plan indicating selections for breakfast, lunch, and dinner; lifestyle recommendations relating to sleep, rest, and relaxation; and finally, suggestions and alternatives to environmental barriers, such as barriers that prevent healthy food shopping or limit reliable transportation to and from appointments with health providers and pharmacy visits.

13.2. Access to Health Insurance and Medication Assistance Plans

Health insurance and medication plan assistance for patients is especially important to improving access to and affordability of medical care and BP medications. Learning how the patient financially supports and budgets for his or her medical care and medications offers the opportunity to share additional insight relating to cost reductions, including restructured payment plans. Ideally, this would improve the patient’s compliance with medication adherence and treatment goals.
13.3. Social and Community Services

Health care can be strengthened through local partnerships. Hypertensive patients, particularly patients with lower incomes, have more opportunity to achieve treatment goals with the assistance of strong local partnerships. In patients with low socioeconomic status or patients who are challenged by social situations, integration of social and community services offers complementary reinforcement of clinically identified treatment goals. Social and community services are helpful when explicitly related to medical care. However, additional financial support and financial services are incredibly beneficial to patients, some of whom may choose to skip a doctor’s appointment to pay a residential utility bill.

15. Evidence Gaps and Future Directions

In the present guideline, the writing committee was able to call on the large body of literature on BP and hypertension to make strong recommendations across a broad range of medical conditions. Nonetheless, significant gaps in knowledge exist. Importantly, there are areas where epidemiological and natural history studies suggest that hypertension prevention or earlier treatment of hypertension might substantially improve outcomes, but clinical trials are lacking to provide guidance. The combination of epidemiological data showing a graded relationship between BP and outcomes, particularly above a BP of 120/80 mm Hg, and the results of the SPRINT trial showing benefit of more comprehensive treatment to a target BP of <120/80 mm Hg, suggests that a lifelong BP below that level will substantially lower CVD and CKD incidence. This is especially the case for younger individuals, those with DM, and those with high lifetime CVD risk based on the presence of multiple risk factors, including high BP. If hard, cardiovascular outcome clinical trials remain the sole driver of evidence-based guidelines, then determining the full benefit of earlier intervention may not be possible because of the cost and length of time needed for intervention. Outcomes may be different if antihypertensive treatment is initiated earlier in the natural history of CVD. DM may provide a population in whom to test this hypothesis. Composite outcomes that include both prevention of events and surrogates, such as prevention of decline in renal function or amelioration of measures of subclinical atherosclerosis, vascular stiffness, or LV structure and function, should be considered. Otherwise, these younger individuals may be undertreated and experience mortality or CVD events before being old enough to enter hard outcome–driven trials such as SPRINT. Replication of SPRINT, especially in younger patients with DM and in countries where nonischemic stroke is the predominant cause of CVD, is highly desirable. Likewise, implementation studies that demonstrate the practicality of SPRINT-like interventions in resource-constrained practice settings are needed.

More information is urgently needed relating hypertensive target organ damage to CVD risk and outcomes. Should the identification of target organ damage and hypertensive heart disease prompt more aggressive BP management (i.e., increase the rationale for instituting pharmacological therapy earlier or more intensively? Should all patients with hypertension be screened with echocardiogram for LVH? Should
echocardiography be repeated once LVH is noted? Is it important to document LVH regression? At present, there are no RCT data to inform guideline recommendations.

ABPM and HBPM provide enhanced ability to both diagnose hypertension and monitor treatment. Although evidence is sufficient to recommend incorporating these tools into clinical practice, more knowledge about them is required. Areas of inquiry include closer mapping of the relationship of outcomes to ambulatory and home BP measurements, so that definitions of hypertension and hypertension severity based on these measures can be developed, including the importance of masked hypertension, white coat hypertension, and nocturnal hypertension. Reproducibility of ambulatory and home BPs must be studied, and cohorts should include a broader range of ethnicities. Trials with entry criteria and treatment goals based on ambulatory or home BP measures should be conducted, including studies of masked and white coat hypertension. The practicality and cost of incorporating ABPM into EHR and routine care should be assessed. The existence of these techniques should not hamper efforts to investigate ways to improve accuracy in the measurement of clinic BP. Further research on improving accuracy of office BP measurements, including number of measurements, training of personnel measuring BP, and device comparisons, will help standardize care and thus improve outcomes. Technology for measurement of BP continues to evolve with the emergence of cuffless devices and other strategies that provide the opportunity for continuous noninvasive assessment of BP. The accuracy, cost, and usefulness of these new technologies will need to be assessed.

The contemporary healthcare environment is dramatically different from the era in which awareness of hypertension as a risk factor and benefits of treatment were discovered. With the advent of the EHR, complex calculations of CVD risk and renal function can be incorporated into routine reports, and many new avenues to support intervention strategies are available to clinicians. Optimizing these approaches will require continued focused research. Recognition that simply applying what we know about BP control would have a large impact on population health, observations on inefficiencies and excessive cost in the U.S. healthcare system, and the growth of information technology have led to promising studies of ways to improve and monitor hypertension care. Results of this research are reflected in this guideline, but further work is required. Examples for study include the effectiveness of multidisciplinary healthcare teams to achieve BP treatment goals at lower cost, social media to maintain contact with patients, information technology to monitor outcomes and decrease practice variability, and incentives to providers to achieve better outcomes for patients. A key goal of these efforts should be to demonstrate reduction in healthcare disparities across ethnicity, sex, social and economic class, and age barriers.

More research on the prevention of the development of hypertension and the benefit of lifetime low BP should be conducted. In this regard, elucidation of genetic expression, epigenetic effects, transcriptomics, and proteomics that link genotypes with longitudinal databases may add considerable knowledge about beneficial outcomes of lifelong lower BP, determinants of rise in BP over time, and identification of new treatment targets through understanding the underlying pathophysiological mechanisms. Research should be directed toward the development of therapies that directly counteract the mechanisms accounting for the development of hypertension and disease progression. Additional research aimed at development of practical approaches to implementation of clinical and population-based strategies to prevent obesity, increase physical fitness, and control excess salt and sugar intake could have significant public health impact. In addition, there are minimal, if any, data on whether treatment of hypertension during pregnancy mitigates risk; thus, there is a need for further research in this area, considering both proximate (during the pregnancy and postpartum period) and distant (CVD prevention) outcomes (1).

In the very old, frailty and higher risk of medication side effects complicate treatment. Additional knowledge of the effects of antihypertensive treatment for patients with dementia and patients who reside in long-term-care facility settings is needed. The best approach to older persons who have supine hypertension but postural hypotension needs to be clarified.

Further research related to shared decision-making with patients and their families is needed. Examples include areas where evidence does not clearly identify one treatment or goal as substantially better
than another, where improved patient knowledge (or improved provider knowledge of the patient’s circumstances) might improve compliance, where reliance on patient collaboration improves achievement of outcomes (e.g., HBPM, use of social media), and where there are competing health concerns (e.g., older individuals with frailty).

Finally, clinical guidelines are increasingly required to manage the large body of accumulated knowledge related to diagnosis and management of high BP. However, guidelines often cause controversy and confusion when competing recommendations are made by different “expert” groups or when changes in definitions, treatments, or treatment goals are introduced. Now may be the time to begin the investigation of the impact of guidelines on clinical practice, costs, and patient outcomes, as well as ways to facilitate communication and collaboration between different guideline-developing organizations. This document is, as its name implies, a guide. In managing patients, the responsible clinician’s judgment remains paramount.

This table represents the relationships of committee members with industry and other entities (RWI) that are considered relevant to this document. Although most ACC/AHA guideline writing committees are constituted such that no more than half the members may have relevant RWI for 1 year before and during development of the guideline, rules for the prevention guidelines require that no members have relevant RWI from 1 year before appointment until 1 year after publication of the guideline. Members’ RWI were
reviewed and updated at all meetings and conference calls of the writing committee during the document development period. The complete ACC/AHA policy on RWI is available at http://www.acc.org/guidelines/about-guidelines-and-clinical-documents/relationships-with-industry-policy.

We gratefully acknowledge the contributions of Dr. Lawrence Appel, who served as a member of the Writing Committee from November 2014 to September 2015.

*Dr. David C. Goff resigned from the writing committee in December 2016 because of a change in employment before the recommendations were balloted. The writing committee thanks him for his contributions, which were extremely beneficial to the development of the draft.

AAPA indicates American Academy of Physician Assistants; ACC, American College of Cardiology; ACPM, American College of Preventive Medicine; AGS, American Geriatrics Society; AHA, American Heart Association; APhA, American Pharmacists Association; ASH, American Society of Hypertension; ASPC, American Society for Preventive Cardiology; ABC, Association of Black Cardiologists; NMA, National Medical Association; and PCNA, Preventive Cardiovascular Nurses Association.

This table represents the relationships of reviewers with industry and other entities that were disclosed at the time of peer review, including those not deemed to be relevant to this document, at the time this document was under review. The table does not necessarily reflect relationships with industry at the time of publication. A person is deemed to have a significant interest in a business if the interest represents ownership of ≥5% of the voting stock or share of the business entity, or ownership of ≥$5,000 of the fair market value of the business entity; or if funds received by the person from the business entity exceed 5% of the person’s gross income for the previous year. Relationships that exist with no financial benefit are also included for the purpose of transparency. Relationships in this table are modest unless otherwise noted. Names are listed in alphabetical order within each category of review. Please refer to [http://www.acc.org/guidelines/about-guidelines-and-clinical-documents/relationships-with-industry-policy](http://www.acc.org/guidelines/about-guidelines-and-clinical-documents/relationships-with-industry-policy) for definitions of disclosure categories or additional information about the ACC/AHA Disclosure Policy for Writing Committees.

* Significant relationship.
† No financial benefit.

This table represents all relationships of committee members with industry and other entities that were reported by authors, including those not deemed to be relevant to this document, at the time this document was under development. The table does not necessarily reflect relationships with industry at the time of publication. A person is deemed to have a significant interest in a business if the interest represents ownership of ≥5% of the voting stock or share of the business entity, or ownership of ≥$5,000 of the fair market value of the business entity; or if funds received by the person from the business entity exceed 5% of the person’s gross income for the previous year. Relationships that exist with no financial benefit are also included for the purpose of transparency. Relationships in this table are modest unless otherwise noted. Please refer to http://www.acc.org/guidelines/about-guidelines-and-clinical-documents/relationships-with-industry-policy for definitions of disclosure categories or additional information about the ACC/AHA Disclosure Policy for Writing Committees.

We gratefully acknowledge the contributions of Dr. Lawrence Appel, who served as a member of the Writing Committee from November 2014 to September 2015.

*Dr. David C. Goff resigned from the writing committee in December 2016 due to a change in employment before the recommendations were balloted. The writing committee thanks him for his contributions, which were extremely beneficial to the development of the draft.

†Significant relationship.

Search Terms:

An extensive evidence review, which included literature derived from research involving human subjects, published in English, and indexed in MEDLINE (through PubMed), EMBASE, the Cochrane Library, the Agency for Healthcare Research and Quality, and other selected databases relevant to this guideline, was conducted between February and August 2015. Key search words included but were not limited to the following: adherence; aerobic; alcohol intake; ambulatory care; antihypertensive: agents, drug, medication, therapy; beta adrenergic blockers; blood pressure: arterial, control, determination, devises, goal, high, improve, measurement, monitoring, ambulatory; calcium channel blockers; diet; diuretic agent; drug therapy; heart failure: diastolic, systolic; hypertension: white coat, masked, ambulatory, isolated ambulatory, isolated clinic, diagnosis, reverse white coat, prevention, therapy, treatment, control; intervention; lifestyle: measures, modification; office visits; patient outcome; performance measures; physical activity; potassium intake; protein intake; renin inhibitor; risk reduction: behavior, counseling; screening; sphygmomanometers; spironolactone; therapy; treatment: adherence, compliance, efficacy, outcome, protocol, regimen; weight. Additional relevant studies published through June 2016, during the guideline writing process, were also considered by the writing committee, and added to the evidence tables when appropriate.
Abbreviations:

1\textsuperscript{st}, primary; 2\textsuperscript{nd}, secondary; AASK, African American Study of Kidney Disease and Hypertension; ABI, ankle-brachial index; ABCD, Appropriate Blood Pressure Control in Diabetes; ABPM, ambulatory blood pressure monitoring; ACCESS, Acute Candesartan Cilexetil Evaluation in Stroke Survivors; ACCOMPLISH, Avoiding Cardiovascular Events Through Combination Therapy in Patients Living With Systolic Hypertension; ACCORD, Action to Control Cardiovascular Risk in Diabetes; ACE, angiotensin-converting enzyme; ACEI, angiotensin-converting enzyme inhibitor; ACS, acute coronary syndrome; ADVANCE, Action in Diabetes and Vascular Disease; AF, atrial fibrillation; AFL, atrial flutter; AHR, adjusted hazard ratio; AIPRD, Angiotensin-Converting Enzyme Inhibition in Progressive Renal Disease; ALLHAT, Antihypertensive Lipid Lowering Treatment to Prevent Heart Attack Trial; AMI, acute myocardial infarction; ARB, angiotensin-receptor blocker; AROC, Atherosclerosis Risk in Communities; ASCOT, Anglo-Scandinavian Cardiac Outcomes Trial; BB, beta blocker; BMI, body mass index; BP, blood pressure; BPLTTC, Blood Pressure Lowering Treatment Trials’ Collaboration; bpm, beats per minute; BUN, blood urea nitrogen; CABB, coronary artery bypass graft; CAD, coronary artery disease; CATIS, China Antihypertensive Trial in Acute Ischemic Stroke; CCB, calcium-channel blocker; CCU, coronary care unit; CHD, coronary heart disease; CHF, congestive heart failure; CHHIPS, Controlling Hypertension and Hypotension Immediately Post-Stroke; CI, confidence interval; CKD, chronic kidney disease; COMFORT, Combination Pill of Losartan Potassium and Hydrochlorothiazide for Improvement of Medication Compliance Trial; COSSACS, the Continue or Stop Post-Stroke Antihypertensives Collaborative Study; CPAP, continuous positive airway pressure; Cr, creatinine; CrCl, creatinine clearance; CRP, c-reactive protein; CR/XL, metoprolol controlled release/extended release; CT, computed tomography; CV, cardiovascular; CVD, cardiovascular disease; DASH, Dietary Approaches to Stop Hypertension; DBP, diastolic blood pressure; DM, diabetes mellitus; DM-1, diabetes mellitus type-1; DM-2, diabetes mellitus type-2; ECG, electrocardiogram; ED, emergency department; EF, ejection fraction; eGFR, estimated glomerular filtration rate; ESKD, end-stage kidney disease; ESRD, end-stage renal disease; FC, functional class; FDC, fixed dose combination; FEVER, Felodipine Event Reduction; GITS, gastrointestinal therapeutic system; GFR, glomerular filtration rate; HBPM, home blood pressure monitoring; HCTZ, hydrochlorothiazide; HDL, high-density lipoprotein; HDL-C, high-density lipoprotein cholesterol; HEDIS, Healthcare Effectiveness Data and Information Set; HF, heart failure; HFpEF, reduced ejection fraction; HFrEF, heart failure with preserved ejection fraction; HIV, human immunodeficiency virus; HR, hazard ratio; HTN, hypertension; ICD, implantable cardioverter-defibrillator; ICH, intracerebral hemorrhage; IDACO, International Database of Ambulatory Blood Pressure in relation to Cardiovascular Outcome; IHD, ischemic heart disease; IMT, intimal media thickness; INDANA, Individual Data Analysis of Antihypertensive drug intervention trials; INTERACT2, the second intensive Blood Pressure Reduction in Acute Cerebral Hemorrhage Trial; INVEST, International Verapamil-Trandolapril Study; INWEST, the Intravenous Nimodipine West European Stroke Trial; IQI, interquartile interval; IQR, interquartile range; IRR, incident rate ratio; ISDN, isosorbide dinitrate; IV, intravenous; JNC-7, 7\textsuperscript{th} Report of the Joint National Committee; KPNC, Kaiser Permanente Northern California; LDL, low-density lipoprotein; LGSAS, low-gradient severe aortic stenosis; LIFE, Losartan Intervention For Endpoint Reduction in Hypertension; LVEF, left ventricular ejection fraction; LVH, left ventricular hypertrophy; LVMI; left ventricular mass index; MACCE, major adverse cardiac and cerebrovascular events; MACE, major adverse cardiac events; MAP, mean arterial pressure; MD, mean difference; MDPIT, Multicenter Diltiazem Postinfarction Research Group; MDRD, Modification of Diet in Renal Disease; MERIT, Metoprolol CR/XL Randomised Intervention Trial; MESA, Multi-Ethnic Study of Atherosclerosis; MH, masked hypertension; MI, myocardial infarction; MOSES, The Morbidity and Mortality After Stroke, Eprosartan Compared With Nitrendipine for Secondary Prevention; MPR, medication possession ratio; MRFIT, Multiple Risk Factor Intervention Trial; MRI, magnetic resonance imaging; N/A, not available; NCQA, National Committee for Quality Assurance; NEMESIS, North East Melbourne Stroke Incidence Study; NHANES, National Health and Nutrition Examination Surveys; NIH, National Institute of Health; NNT, number needed to treat; NR, not relative;
NS, nonsignificant; NSAID, nonsteroidal anti-inflammatory drug; NUTRICODE, Nutrition and Chronic Diseases Expert Group; NYHA, New York Heart Association; ONTARGET, Ongoing Telmisartan Alone and in Combination With Ramipril Global Endpoint Trial; OR, odds ratio; OSA, obstructive sleep apnea; P4P, pay for performance; PA, pulmonary artery; PAD, peripheral artery disease; PAMELA, Pressione Arteriose Monitorate E Loro Associazioni; PCP, primary care provider; periop, perioperative; PREDIMED, Prevention with a Mediterranean Diet; PRISMA, Preferred Reporting Items for Systematic Reviews and Meta-Analyses; PROBE, Prospective, randomized, open, blinded endpoint; PROGRESS, The perindopril protection against recurrent stroke study; PRONTO, Prospective Optical Coherence Tomography Imaging of Patients with endovascular Age-Related Macular Degeneration Treated with Intraocular Ranibizumab; pt, patient; PTCA, percutaneous transluminal coronary angioplasty; PVD, peripheral vascular disease; QI, quality improvement; RAAS, renin angiotensin aldosterone system; RCT, randomized controlled trial; REIN-2, Blood Pressure Control for Renoprotection in Patients with Non-diabetic Renal Disease; RH, relative hazard; ROADMAP, Randomized Olmesartan and Diabetes Microalbuminuria Prevention; RR, relative risk; Rx, medical prescription; SAE, severe adverse event; SBP, systolic blood pressure; SCOPE-AS, Symptomatic Cardiac Obstruction – Pilot Study of Enalapril in Aortic Stenosis; SD, standard deviation; SE, stress echocardiography; SH, sustained hypertension; SHEP, Summer Health Enrichment; SITS-ISTR, Safe Implementation of Thrombolysis in Stroke-International Stroke Thrombolysis Register; SKIPOGH, Swiss Kidney Project on Genes in Hypertension; SPC, single pill combination; SPRINT, Systolic Blood Pressure Intervention Trial; Syst-Eur, Systolic Hypertension in Europe; t-PA, tissue plasminogen activator; TIA, transient ischemic attack; TOHP, Trials of Hypertension Prevention; TOMHS, Treatment of Mild Hypertension Study; TONE, Trial of Nonpharmacologic Intervention in the Elderly; TOPCAT, Treatment of Preserved Cardiac Function Heart Failure With Aldosterone Antagonist; TR, target range; UA, unstable angina; U.K., United Kingdom; UKPDS, United Kingdom Prospective Diabetes Study; U.S., United States; VA, Veterans Affairs; VA Coop, Veterans Administration Cooperative Study Group on Antihypertensive Agents; VA NEPHRON-D, Veterans Affairs Nephropathy in Diabetes; VALIANT, Valsartan in Acute Myocardial Infarction Trial; VALUE, Valsartan Antihypertensive Long-term Use Evaluation; WCH, white coat hypertension; and WPW; Wolff-Parkinson-White syndrome.

<tr>
<td>Lewington S, et al., 2002 12493255</td>
<td>Study type: Meta-analysis of 61 observational cohort studies</td>
<td>Inclusion criteria: Men and women with no history of previous CVD and record of key study variables. Exclusion criteria: Prior CVD</td>
<td>1° endpoint: Cause-specific mortality Results: 958,074 persons followed for a mean of 12 y to death (12.7 million person-y at risk. Number of deaths attributed to: -Stroke: 11960 -IHD: 34,283 -Other vascular:10092 -Non-vascular: 60797 Above a SBP ≥115 mm Hg and DBP ≥75 mm Hg, there was a progressive rise in vascular death with progressively high BP with no evidence of a J-curve (approximately doubling of stroke and IHD mortality for a 20 mm Hg higher level of SBP or 10 mm Hg higher level of DBP, in those 40–69 y). With progressively higher age, the BP-related proportional risk of vascular mortality was somewhat reduced but the corresponding absolute risk was much higher.</td>
<td>• In adults aged 40–89 y, usual BP is strongly related to vascular (and overall) mortality, without evidence of a threshold down to at least an SBP/DBP of 115/75 mm Hg.</td>
</tr>
<tr>
<td>Rapsomaniki E, et al., 2014 24881994</td>
<td>Study type: Observational cohort study Size: 1.25 million patients, in 225 primary care practices in the UK, followed for a median of 5.2 y using electronic medical records.</td>
<td>Inclusion criteria: Men and women ≥30 y, with no previous diagnosis of CVD, who had been registered at their practices for ≥1 year. Exclusion criteria: N/A</td>
<td>1° endpoint: 12 acute and chronic CVD outcomes Results: 83,098 initial CVD events recorded. Within each of 3 age groups (30–59, 60–79, and ≥80 y), the lowest risk for CVD was in those with a SBP 90–114 mm Hg and DBP 60–74 mm Hg. There was a direct relationship between level of BP and most CVD outcomes, with no evidence of J-curve, with the strongest relationship for SBP and stroke and weakest for abdominal aneurysm.</td>
<td>• Despite modern treatments, the lifetime burden of BP-related CVD was substantial.</td>
</tr>
<tr>
<td>Wilson PW, et al., 1999 (1) 10335688</td>
<td>Study type: Nonrandomized</td>
<td>Inclusion criteria: Men and women 18–74 y and free of CHD at baseline, from the Framingham Offspring Study</td>
<td>1° endpoint: Total CHD (first occurrence of angina, UA, MI, and coronary death), Hard CHD (first MI and coronary death)</td>
<td>• CVD risk factors infrequently occur in isolation (only 28%–30% of the time)</td>
</tr>

### Huang Y, et al., 2013 (5)

| Study type: | Meta-analysis of nonrandomized studies |
| Size: | 468,561 pts from 18 prospective cohort studies |
| Inclusion criteria: | Studies reporting risk for CVD, CHD and stroke, with 120–139/80–89 mm Hg, 120–129/80–84 mm Hg or 130–139/85–89 mm Hg |
| Adults ≥18 y BP evaluated at baseline |
| Exclusion criteria: | N/A |
| 1° endpoint: | CVD, CHD, and stroke |
| Results: | Comparing SBP/DBP 120–129/80–84 mm Hg to <120/80 mm Hg: |
| | - CVD: RR: 1.46; 95% CI: 1.32–1.62 |
| | - Compared to pts with SBP/DBP <120/80 mm Hg, the RR for CVD, MI and stroke were larger for pts with SBP/DBP of 130–139/85–89 mm Hg vs. SBP/DBP of 120–129/80–84 mm Hg. |

---

| Size: | 2,406 men, 2,569 women (1,759 men, 1,818 women with follow-up) |
| Exclusion criteria: | N/A |
| Results: | Presence of ≥3 risk factors was associated with a 2.39 times greater risk of CHD in men (95% CI: 1.56–3.36; p<0.001) and a 5.90 increased risk of CHD in women (95% CI: 2.54–13.73; p<0.001) |
| Presence of ≥3 risk factors occurred 17% of the time in both men and women |
| Presence of ≥3 risk factors associated with high risk of CHD and coronary death (attributable risk of 20% in men and 48% in women) |
Huang Y, et al., 2014 (6) 24074825

| Study type: Meta-analysis of nonrandomized studies | Inclusion criteria: Studies reporting adjusted risk for ESRD with 120–139/80–89 mm Hg, 120–129/80–84 mm Hg or 130–139/85–89 mm Hg. Adults ≥18 y BP evaluated at baseline ≥1 y follow-up for ESRD. Results reported with adjustment. | Exclusion criteria: 1) enrollment depended on having a condition or risk factor; 2) the study reported only age- and sex-adjusted RRs; and 3) data were derived from the same cohort or from a meta-analysis. | 1° endpoint: ESRD | Results: Comparing SBP/DBP 120–129/80–84 mm Hg to <120/80 mm Hg:  
- ESRD RR: 1.44; 95% CI: 1.19–1.74  
- p value comparing these risk ratios = 0.001. | SBP/DBP of 120–129/80–84 mm Hg

Huang Y, et al., 2013 (7) 24623843

| Study type: Meta-analysis of nonrandomized studies | Inclusion criteria: Studies reporting adjusted risk for stroke with 120–139/80–89 mm Hg, 120–129/80–84 mm Hg or 130–139/85–89 mm Hg. Adults ≥18 y BP evaluated at baseline ≥1 y follow-up for stroke. Results reported with adjustment. | Exclusion criteria: 1) enrollment depended on having a specific risk factor condition (e.g., DM or other baseline chronic diseases); 2) The RR was unadjusted or only adjusted for age and sex; and 3) data were derived from the same cohort or meta-analysis of other cohort studies. | 1° endpoint: Stroke | Results: Comparing SBP/DBP 120–129/80–84 mm Hg to <120/80 mm Hg:  
- Stroke: RR: 1.44; 95% CI: 1.27–1.63  
- p value comparing these risk ratios = 0.001. | SBP/DBP of 120–129/80–84 mm Hg

<thead>
<tr>
<th>Limitations:</th>
</tr>
</thead>
<tbody>
<tr>
<td>• BP-lowering significantly reduces vascular risk across various baseline BP levels and comorbidities. Our results provide strong support for lowering BP to SBP&lt;130 mm Hg and providing BP-lowering treatment to individuals with a history of CVD, CHD, stroke, DM, HF, and CKD.</td>
</tr>
<tr>
<td>• In stratified analyses, we saw no strong evidence that proportional effects were diminished in trials that included people with lower baseline SBP (&lt;130 mm Hg), and major CV events were clearly reduced in high-risk pts with various baseline comorbidities. Both of these major findings—the efficacy of BP-lowering below 130 mm Hg and the similar proportional effects in high risk populations—are consistent with and extend the findings of the SPRINT trial.</td>

</table>

**Study type:** Meta-analysis of use of BP-lowering drugs in prevention of CVD from 147 randomized trials  
**Size:** Of 147 randomized trials of 464,000 pts, 37 trials of BBs in CAD included 38,892 pts, and 37 trials of other antihypertensive drugs in CAD included 85,395 pts  
**Inclusion criteria:** The database search used Medline (1966 to Dec. 2007) to identify randomized trials of BP-lowering drugs in which CAD events or strokes were recorded. The search also included the Cochrane Collaboration and Web of Science databases and the citations in trials and previous meta-analyses and review articles.  
**Exclusion criteria:** Trials were excluded if there were <5 CAD events and strokes or if treatment duration was <6 mo.  
**1° endpoint:** CAD events; stroke  
**Results:** In 37 trials of pts with a history of CAD, BB reduced CAD events 29% (95% CI: 22%–34%). In 27 trials in which BBs were used after acute MI, BB reduced CAD events 31% (95% CI: 24%–38%), and in 11 trials in which BB were used after long-term CAD, BB insignificantly reduced CAD events 13%. In 7 trials, BB reduced stroke 17% (95% CI: 1%–30%). CAD events were reduced 14% (95% CI: 2%–25%) in 11 trials of thiazide diuretics, 17% (95% CI: 11%–22%) in 21 trials of ACEIs, insignificantly 14% in 4 trials of angiotensin receptor blockers, and 15% (95% CI: 8%–22%) in 22 trials of CCB. Stroke was reduced 38% (95% CI: 28%–47%) in 10 trials of thiazide diuretics, 22% (95% CI: 8%–34%) in 13 trials of ACEI, and 34% (95% CI: 25%–42%) in 9 trials of CCB.

**Aim:** To investigate whether pharmacologic BP reduction prevents CV events and deaths in pts with grade 1 HTN.  
**Inclusion criteria:** RCTs of at least 1 y duration; pts ≥18 y, at least 80% of whom had grade 1 HTN and no previous CVD (MI, angina pectoris, CABG, PCI, stroke, TIA, carotid surgery, peripheral arterial  
**1° endpoint:** Total major CV events, comprising stroke (nonfatal stroke or death from cerebrovascular disease), coronary events (nonfatal MI or death from CHD, including sudden death), HF (causing death or resulting in...
**Study type:** Meta-analysis of RCTs  
**Size:** 10 RTCs with 15,266 pts  
**Inclusion criteria:** Intentional BP-lowering comparing active drug treatment with placebo, or less active treatment (intentional BP-lowering trials), or comparison of an active drug with placebo over baseline antihypertensive treatment, resulting in a BP difference of at least 2 mm Hg in either SBP or DBP (nonintentional BP-lowering trials); enrolling of hypertensive individuals only or a high proportion (at least 40%) of them.  
**Exclusion criteria:** N/A  
**1st endpoint:**  
- As some trials were done on low-risk pts, others on higher risk pts, no evaluation of absolute risk-reduction was made. However, a 2nd analysis was done including trials or trial subgroups with mean baseline SBP/DBP values in grade 1 range and a low-to-moderate risk (<5% CV deaths in 10 y in controls): FEVER stratum with baseline SBP below the median (<153 mm Hg); HTN Detection and Follow-up Program stratum with baseline DBP 90–94 mm Hg and no CVD; OSLO (e17); TOMHS (e28) and USPHS. Risks of stroke, CHD, the composite of stroke and CHD, and all-cause death were significantly reduced by BP-lowering in these low-to-moderate risk pts (control group: average CV mortality 4.5% in 10 y) with a moderate BP elevation (average SBP/DBP 145.5/91 mm Hg) at randomization. Standardized RR associated with 10/5 reduction in BP: stroke 0.33 (95% CI: 0.11–0.98) CHD 0.68 (95% CI: 0.48–0.95)  
**Other endpoints:**  
Each of the above outcomes independently; and total deaths.  
- CHD 0.91 (95% CI: 0.74–1.12)  
- Stroke 0.72 (95% CI: 0.55–0.99)  
- HF 0.80 (95% CI: 0.57–1.12)  
- CVD deaths 0.75 (95% CI: 0.57–0.98)  
- Total deaths 0.78 (95% CI: 0.67–0.92)  

Only the first event for a pt was used for the analysis of each outcome, but a pt who had >1 outcome type could contribute to more than 1 analysis. They also tabulated overall withdrawals and withdrawals due to adverse events.  

**Meta-analyses favor BP-lowering treatment even in grade 1 HTN at low-to-moderate risk, and lowering SBP/DBP to <140/90 mm Hg.**  
**Achieving <130/80 mm Hg appears safe, but only adds further reduction in stroke.**
### Aim:
To assess the efficacy and safety of intensive BP-lowering strategies.

### Study type:
Meta-analysis of RCTs

### Size:
19 RCTs with 44,989 pts

### Inclusion criteria:
RCTs with at least 6 mo follow-up that randomly assigned pts to more intensive vs. less intensive BP-lowering treatment, with different BP targets or different BP changes from baseline. Reference lists from identified trials and review articles were manually scanned to identify any other relevant studies.

### Exclusion criteria:
N/A

### Intervention:
BP-lowering meds

### Comparator:
- Less intensive treatment
- BP difference 6.8/3.5
- The mean follow-up BP levels in the less intensive BP-lowering

### 1° endpoint:
- CVD, other major CV events, defined as a MI, stroke, HF, or CV death, separately and combined; nonvascular and all-cause mortality; ESKD, and adverse events. Progression of albuminuria (defined as new onset of microalbuminuria/macro-albuminuria or a change from micro-albuminuria to macro-albuminuria) and retinopathy (retinopathy progression of 2 or more steps) were also recorded for trials that were done in pts with DM
- CVD RR: 0.86 (95% CI: 0.78–0.96)

### Other endpoints:
- MI RR: 0.87 (95% CI: 0.76–1.00) p=0.042
- Stroke RR: 0.78 (95% CI: 0.68–0.90)
- HF RR: 0.85 (95% CI: 0.66–1.11)
- CVD death RR: 0.91 (95% CI: 0.74–1.11)
- Total deaths RR: 0.91 (95% CI: 0.81–1.03)

### Limitations:
- Lack of individual pt data, which would have allowed a more reliable assessment of

| **Aim:** To assess the efficacy and safety of intensive BP-lowering strategies. | **1° endpoint:** CVD death 0.57 (95% CI: 0.32–1.02) total death 0.53 (95% 0.35–0.80) • Compared outcomes of achieved on study SBP <130 vs. ≥130
Standardized Risk ratio associated with 10/5 reduction in BP: stroke 0.68 (95% CI: 0.57, 0.83)
CHD 0.87 (95% CI: 0.76, 1.00)
HF 0.92 (95% CI: 0.47, 1.77)
CVD 0.81 (95% CI: 0.67, 1.00)
CVD death 0.88 (95% CI: 0.77, 1.01) total death 0.88 (95% CI: 0.77, 0.99) • Outcomes of achieved on study SBP 130-139 vs. ≥140
Standardized RR associated with 10/5 reduction in BP: stroke 0.63 (95% CI: 0.52, 0.77)
CHD 0.77 (95% CI: 0.70, 0.86)
HF 0.76 (95% CI: 0.47, 1.25)
CVD 0.74 (95% CI: 0.62, 0.88)
CVD death 0.81 (95% CI: 0.67, 0.97) total death 0.87 (95% CI: 0.75, 1.00) • Similar pattern of results for on treatment DBP. | **Intensive BP-lowering, including to <130 mm Hg, provided greater vascular protection than standard regimens.**
**In high-risk pts, there are additional benefits from more intensive BP-lowering, including for those with SBP <140 mm Hg at baseline.**
**The net absolute benefits of intensive BP-lowering in high-risk individuals are large.**

---

© 2017 American College of Cardiology Foundation and American Heart Association, Inc.
regimen group were 140/81 mm Hg, compared with 133/76 mm Hg in the more intensive treatment group.

**Other results:**
- Benefit for CVD not different by baseline SBP
  - 120–139: 0.89 (95% CI: 0.76–1.05)
  - 140–160: 0.83 (95% CI: 0.68–1.00)
  - >160: 0.89 (95% CI: 0.73–1.09)
- p-heterogeneity: 0.60
- Benefit for CVD not different for more intensive and less intensive targets in intensive group
  - <140 or <150 mm Hg: 0.76 (95% CI: 0.60–0.97)
  - <120–<130 mm Hg: 0.91 (95% CI: 0.84–1.00; p-hetero: 0.06)
- Absolute benefits were proportional to absolute risk.
- For trials in which all pts had vascular disease, renal disease, or DM at baseline, the average control group rate of major vascular events was 2.9% per y compared with 0.9% per y in other trials, and the numbers needed to treat were 94 (95% CI: 44–782) in these trials vs. 186 (95% CI: 107–708) in all other trials.
- Increase in Severe hypotension: 0.3% vs. 0.1% per person y OR: 2.68 (95% CI: 1.21–5.89)

**Interpretation:** Supports treating pt with and without CVD at threshold of 130 to <130. Supports treating at threshold of about 130 even down to a CVD event rate of 0.9% per y.

---

| Uhlig K, et al., 2012 (23) 22439158 | Systematic review  
Self-monitoring vs. usual care vs. self-monitoring+support | N/A | • Self-monitoring vs. usual care resulted in lower SBP/DBP (-3.1/-2.0 mm Hg) at 6 mo  
• Self-monitoring + support vs. usual care resulted in lower SBP/DBP SBP/DBP -3.4-- -8.9/-1.9-- -4.4 mm Hg up to 12 mo.  
• Self-monitoring may confer a small benefit for BP control. |
| McManus RJ, et al., 2014 (24) 25157723 | RCT  
Self-monitoring with self-titration vs. usual care. | SBP/DBP ≥130/85 mm Hg | • Self-monitoring with self-titration was associated with SBP and DBP differences of 9.2 mm Hg and 3.4 mm Hg, respectively. |
| Margolis KL, et al., 2013 (25) 23821088 | Cluster RCT  
Pts from 16 clinics in integrated health system in Minneapolis, MN  
Intervention included 12 mo of home BP tele-monitoring and pharmacist case management, with 6 mo of follow-up afterward | 222 pts randomized to 8 usual care clinics and 228 randomized to 8 intervention clinics  
Intervention group achieved better BP control compared to usual care during 12 mo of intervention and persisting during 6 mo of follow-up  
SBP was <140/90 in 57.2% (95% CI: 44.8%, 68.7%) of intervention pts at 6 and 12 mo vs. 30% (95% CI: 23.2%, 37.8%) in usual care (p=0.001)  
• Combination of home BP tele-monitoring and pharmacist case management helped control HTN better than usual care at 6, 12, and 18 mo.24 |
| Margolis KL, et al., 2013 (25) 23821088 | RCT  
Home BP telemonitoring with pharmacist case management vs. usual care. | Uncontrolled BP  
SBP/DBP <140/90 mm Hg (<130/80 mm Hg in DM or CKD) at 6 and 12 mo. | • Telemonitoring resulted in better BP control (57% vs. 30%) at 6 and 12 mo and larger SBP declines at 6, 12, and 18 mo.  
• Some aspects of pt satisfaction (e.g., clinicians listening carefully) improved with telemonitoring. |
| McManus RJ, et al., 2014 (24) 25157723 | RCT  
Self-monitoring with self-titration vs. usual care. | SBP/DBP ≥130/85 mm Hg | • Self-monitoring with self-titration was associated with SBP and DBP differences of 9.2 mm Hg and 3.4 mm Hg, respectively. |

<td>Barb F, et al., 2010 (57) 20007932</td>
<td>Aim: Assess the effect on BP of 1 y of treatment with CPAP in nonsleepy pts with HTN and OSA.</td>
<td>Inclusion criteria: Pts with HTN (on medications or ≥140/90) and</td>
<td>Intervention: CPAP Comparator: Conservative treatment</td>
<td>1° endpoint: Decrease in BP Results: At 12 mo, CPAP decreased SBP by 1.89 mm Hg (95% CI: 3.90–0.11 mm Hg; p=0.065) and DBP 2.19 mm Hg</td>
<td>Limitations: Not blinded; both groups consisted of pts with severe sleep-apnea.</td>
</tr>
</tbody>
</table>
### Martinez-Garcia MA, et al., 2013

**Aim:** Assess the effect of CPAP on BP in pts with OSA and resistant hypertension.

**Study type:** RCT  
**Size:** 359 pts; 12 mo of follow-up  
**Inclusion criteria:** apnea-hypopnea index >19. (dietary counseling and sleep hygiene advice). (95% CI: 3.46 - 0.93 mm Hg; p=0.001). The most significant reduction in BP was in pts who used CPAP for more than 5.6 h/night.

**Intervention:** CPAP  
**Comparator:** No therapy  
**1° endpoint:** Change in 24-h ABPM from baseline to 12 wk.

**Results:**
- When the changes in BP were compared between groups by intent to treat, the CPAP group achieved a greater decrease in 24-h mean BP (3.1 mm Hg (95% CI: 0.6, 5.6); p=0.02) and 24-h DBP (3.2 mm Hg (95% CI: 1.0, 5.4; p=0.005) but not in 24-h SBP (3.1 mm Hg (95% CI: -0.6–6.7; p=0.10) compared to control.
- There was also a greater nocturnal BP dipping pattern in CPAP treated pts than control (35.9% vs. 21.6%; adjusted OR: 2.4; CI: 1.2–5.1; p=0.02).
- There was a significant positive correlation between h of CPAP use and the decrease in mean 24-h BP (r=0.29; 0.006), SBP (r=0.25; p=0.02) and DBP (r=0.30; p=0.005).

**Limitations:** Did not use sham CPAP as placebo; open-label; short follow-up.

**Conclusions:** CPAP induced a significant reduction in BP, albeit small, in hypertensive pts with OSA.

### Lozano L, et al., 2010

**Aim:** Assess effect of CPAP on pts with OSA and resistant hypertension.

**Study type:** RCT  
**Size:** 96 pts; 3 mo of follow-up  
**Inclusion criteria:** Pts with resistant hypertension and OSA.

**Intervention:** CPAP + conventional drug treatment  
**Comparator:** Conventional drug treatment alone  
**1° endpoint:** Decrease in 24-h ABPM from baseline to 12 wk.

**Results:** Pts with ABPM confirmed resistant hypertension treated with CPAP, unlike those treated with conventional therapy, showed a decrease in 24-h DBP (-4.9±6.4 vs. 0.1±7.3 mm Hg; p=0.027). Pts who used CPAP >5.8 h showed a greater reduction in daytime DBP (-6.12 mm Hg; 95% CI: -1.45–10.82; p=0.004), 24-h DBP (-6.98 mm Hg; 95% CI: -12.1; p=0.009) and 24-h SBP (-9.71 mm Hg; 95% CI: -0.20– -19.22; p=0.46).

**Limitations:** Small study; only 3 mo follow-up; lack of sham control.

**Conclusions:** CPAP as a complement to usual treatment improved mean 24-h DBP in pts with OSA and ABPM-confirmed resistant hypertension.
Muxfeldt ES, et al., 2015 (60) 25601933

**Aim:** Evaluate the effect of CPAP on pts with resistant hypertension and OSA.

**Study type:** RCT

**Size:** 434 pts; 6 mo of follow-up

**Inclusion criteria:** Pts with resistant hypertension and OSA

**Intervention:** CPAP + conventional antihypertensive therapy

**Comparator:** Antihypertensive therapy alone. Conventional antihypertensive therapy included spironolactone.

**1° endpoint:** BP reduction at 6 mo via ABPM

**Results:**
- On an intention-to-treat analysis, there was no significant difference in any BP change, neither in nocturnal BP fall, between CPAP and control groups. The best effect of CPAP was on night-time SBP in per-protocol analysis, with greater reduction of 4.7 mm Hg (95% CI: -1.6%–5.8%; p=0.25, in comparison with the control group.
- Median use of CPAP was 4.8 h.

**Limitations:** Nonblinded design; per protocol analysis underpowered to show the prespecified outcome of 6–7 mm Hg SBP differences between CPAP and control groups.

**Conclusions:** CPAP had no significant effect on clinic or ambulatory BP in pts with resistant hypertension and moderately severe to severe OSA. However, in the specific subgroup of pts with uncontrolled ambulatory BP, CPAP may modestly reduce night-time SBP and improve the nocturnal BP fall pattern. The reason for lack of BP reduction in the overall study may have been due to excellent control of BP with median 5 medications, including spironolactone, in the majority of pts.

Pedrosa RP, et al., 2013 (61) 23598607

**Aim:** Evaluate the effect of CPAP on pts with resistant hypertension and OSA.

**Study type:** RCT with

**Size:** 40 pts; 6 mo follow-up

**Inclusion criteria:** Pts with resistant hypertension and OSA

**Intervention:** CPAP + conventional antihypertensive therapy (n=20)

**Comparator:** Antihypertensive therapy alone (n=20).

**1° endpoint:** BP reduction at 6 mo by ABPM.

**Results:** BP was 162±4/97±2 mm Hg prior to randomization. CPAP was used for 6 h/night. Compared with the control group, awake SBP/DBP decreased significantly in the CPAP group (-6.5±3.3/-4.5±1.9 vs. +3.1±3.3/-2.1±2.7 mm Hg; p<0.05). BP changes were significant only when pts were awake but not at night by ABPM.

**Limitations:** Small; but strength was rigorous exclusion of pts who were nonadherent; control arm did not undergo placebo treatment; nonblinded.

**Conclusions:** Treatment of OSA with CPAP significantly reduces daytime BP in pts with resistant hypertension.

---

**Data Supplement 9. RCTs Studying the Effect of Nonpharmacologic Interventions on BP (Dietary Fiber Intake) (Section 6.2)**

| Whelton SP, et al., 2005 (62) | Aim: Study the effect of dietary fiber intake on BP  
Study type: Systematic review and meta-analysis  
Size:  
- 21 RCTs (25 comparisons) with 1,477 pts  
- 20 of the RCTs were conducted in nonhypertensive persons  
- 13 double-blind; 3 single blind and 9 open label  
Inclusion criteria:  
- RCT  
- ≥16 y  
- English language publication before Feb. 2004  
- No concurrent interventions  
Exclusion criteria:  
- Missing key data  
Intervention: Fiber supplementation, either as a pill (8 trials), cereal/fruit/veg (15 trials), Pectin (1 trial), Guar gum (1 trial)  
Comparator: Placebo or no fiber supplementation  
1° endpoint: In a pooled analysis of the overall group (hypertensive and normotensive persons), the mean for change in SBP was -1.15 mm Hg; 95% CI: -2.68–0.39 mm Hg and for DBP was -1.65 mm Hg; 95% CI: -2.70– -0.61 mm Hg. In the subgroup of 20 trials conducted in nonhypertensives, the mean change in SBP was -0.14 mm Hg; 95% CI: -1.10–0.86 mm Hg. In the subgroup of 5 trials conducted in hypertensives, the mean change in BP was -5.95 mm Hg; 95% CI: -9.50– -2.40 mm Hg.  
Safety endpoint: N/A  
● This is the most detailed and comprehensive review of the topic.  
● It provides limited evidence, overall, that fiber supplementation results in a significant in BP and suggests no evidence in support of an effect in normotensives. |  
| Streppel MT, et al., 2005 (63) | Aim: Study the effect of fiber supplementation on BP  
Study type: Systematic review and meta-analysis  
Size:  
- 23 RCTs (25 comparisons) in 1,404 pts  
- Mean duration=9 wk  
- Mean age=42 y  
- 16 double-blind, with 14 (67%) of the 21 comparisons conducted in normotensive pts  
- 3 trials based on plant protein and 4 trials based on animal protein  
Inclusion criteria:  
- Human RCT  
- BP 1° or 2° outcome  
Exclusion criteria:  
- Inadequate reporting of the data  
- Concurrent intervention  
Intervention: Fiber supplementation (average dose=11.5 g/d); soluble fiber in 11 trials, insoluble fiber in 7 trials, and a mixture in the remaining trials  
Comparator: Placebo or no fiber supplementation  
1° endpoint: In the overall group (hypertensive and normotensive pts), a pooled analysis identified a MD for change in SBP of -1.13 mm Hg; 95% CI: -2.49–0.23. In a subgroup of 17 trials conducted in “nonhypertensives” (mean baseline BP<140/90 mm Hg or <50% receiving antihypertensive medication), the mean treatment effect was -0.23 mm Hg; 95% CI: -1.43–0.98 in univariate analysis and -1.00 mm Hg; 95% CI: -1.94– -0.06 mm Hg in multivariate analysis that adjusted for age, sex, study design, duration of intervention, and fiber dose. The corresponding effects in 8 trials conducted in hypertensives were -4.53 mm Hg; 95% CI: -6.69– -2.38 mm Hg; and -2.42 mm Hg; 95% CI: -5.28–0.45 mm Hg.  
Safety endpoint: N/A  
● Findings consistent with experience in the meta-analysis by Whelton et al. |
Evans CE, et al., 2011 (64)
25668347

Aim: Study the effect of fiber supplementation on BP

Study type: Systematic review and meta-analysis

Size: 28 trials met the inclusion criteria and reported fiber intake and SBP and/or DBP. 18 trials were included in a meta-analysis.

Inclusion criteria
• RCTs, in humans of at least 6 wk duration
• Fiber isolate or fiber-rich diet against a control or placebo
• Published between 1 January 1990 and 1 December 2013.

Exclusion criteria: N/A

Intervention: Fiber supplementation (average dose =11.5 g/d) -soluble fiber in 11 trials, insoluble fiber in 7 trials, and a mixture in the remaining trials

Comparator: Placebo or no fiber supplementation

1° endpoint: Studies were categorized into 1 of 12 fiber-type categories. The pooled estimates for all fiber types were -0.9 mm Hg (95% CI: -2.5–0.6 mm Hg) and -0.7 mm Hg (95% CI: -1.9–0.5 mm Hg) for SBP and DBP, respectively. The median difference in total fiber was 6g.

Analyses of specific fiber types concluded that diets rich in beta-glucans reduce SBP by 2.9 mm Hg (95% CI: 0.9, 4.9 mm Hg) and DBP by 1.5 mm Hg (95% CI: 0.2–2.7 mm Hg) for a median difference in beta-glucans of 4 g. Heterogeneity for individual fiber types was generally low.

Safety endpoint: N/A

Data Supplement 10. RCTs Studying the Effect of Nonpharmacologic Interventions on BP (Fish Oil) (Section 6.2)

<td>In a subsequent meta-analysis of 23 trials, Geleijnse JM, Kok FJ, and Grobbee DE (J Hum Hypertens. 2003;17:471-480) reported a similar effect of potassium on SBP in both hypertensives and nonhypertensives (mean of -3.2 and -1.4 mm Hg, respectively).</td>
</tr>
</tbody>
</table>
### 2017 Hypertension Guideline Data Supplements

- Overall, 33 RCTs (n=2,609)
- 2 RCTs (n=1,049) in normotensives

In normotensives:
- Placebo in 10 RCTs and usual diet in 2 RCTs

In the 20 trials conducted in hypertensives:
- Mean change: SBP -4.4 mm Hg; 95% CI: -6.6– -2.2
- Mean change: DBP -2.5 mm Hg; 95% CI: -4.9– -0.1

Safety endpoint: N/A

In the 1 RCT conducted in African-Americans (n=87):
- Mean change: SBP -6.9 mm Hg; 95% CI: -9.3– -4.4 (p<0.001)
- Mean change: DBP -2.5 mm Hg; 95% CI: -4.3– -0.8 (p=0.004)

In the entire cohort (trials conducted in pts with HTN and normotension), net changes in SBP and DBP were directly related to level of urinary sodium excretion during the trial.

---

### Aburto NJ, et al., 2013 (68)

**Aim:** Study the effect of potassium supplementation on BP

**Study type:** Systematic review and meta-analysis

**Size:** 21 RCTs (n=1,892); 16 in pts with HTN (n=818) and 3 RCTs in pts without HTN (n=757)

**Inclusion criteria:**
- RCT in humans
- Duration ≥4 wk
- 24-h collections of urinary potassium
- No concomitant interventions

**Exclusion criteria:**
- Pts who were acutely ill, HIV positive, hospitalized, or had impaired urinary excretion of potassium

**Intervention:** Potassium supplementation in 20 trials, supplements plus diet/education in 1 trial, and diet/education alone in 2 trials.

**Comparator:** No potassium supplementation (placebo or usual diet)

**Endpoints:**
- Overall change in SBP: -5.93 mm Hg; 95% CI: -10.15– -1.70
- After removing outlier trials, the change was -3.49 mm Hg; 95% CI: -5.15– -1.82 mm Hg.
- In the 19 trials conducted in hypertensives, change in SBP was -3.51 mm Hg; 95% CI: -5.31– -1.72
- In the 3 trials conducted in persons without HTN, change in SBP was 0.09 mm Hg; 95% CI: -0.77–0.95

**Safety endpoint:** N/A

**1° endpoint:**
- Overall change in SBP: -5.93 mm Hg; 95% CI: -10.15– -1.70. After removing outlier trials, the change was -3.49 mm Hg; 95% CI: -5.15– -1.82 mm Hg.
- In 16 trials conducted in hypertensives, change in SBP was -3.51 mm Hg; 95% CI: -5.31– -1.72
- In the 3 trials conducted in persons without HTN, change in SBP was 0.09 mm Hg; 95% CI: -0.77–0.95

**Safety endpoint:** N/A

**1° endpoint:**
- Overall change in SBP: -2.42 mm Hg; 95% CI: -3.75– -1.08
- In the 19 trials conducted in hypertensives, change in SBP was -3.51 mm Hg; 95% CI: -5.31– -1.72
- In the 3 trials conducted in persons without HTN, change in SBP was 0.97 mm Hg; 95% CI: -3.07–1.14

**Safety endpoint:** N/A

**1° endpoint:**
- Overall change in SBP: -2.42 mm Hg; 95% CI: -3.75– -1.08

**Safety endpoint:** N/A

**1° endpoint:**
- Overall change in SBP: -2.42 mm Hg; 95% CI: -3.75– -1.08

**Safety endpoint:** N/A

---

### Geleijnse JM, et al., 2003 (69)

**Aim:** Study the effect of potassium supplementation on BP

**Study type:** Systematic review and meta-regression analysis

**Size:** 27 RCTs; 19 in pts with HTN and 11 RCTs in pts without HTN

**Inclusion criteria:**
- RCT in adults
- Published after 1966
- Duration ≥2 wk
- No concomitant interventions

**Exclusion criteria:**
- Disease
- Outlier results (1 trial)

**Intervention:** Potassium supplementation

**Comparator:** No potassium supplementation

**Endpoints:**
- Overall change in SBP: -2.42 mm Hg; 95% CI: -3.75– -1.08
- In the 19 trials conducted in hypertensives, change in SBP was -3.51 mm Hg; 95% CI: -5.31– -1.72
- In the 3 trials conducted in persons without HTN, change in SBP was 0.97 mm Hg; 95% CI: -3.07–1.14

**Safety endpoint:** N/A

**1° endpoint:**
- Overall change in SBP: -2.42 mm Hg; 95% CI: -3.75– -1.08

**Safety endpoint:** N/A

| Rebholz CM, et al., 2012 (70) 23035142 | **Aim:** Study the effect of protein intake on BP **Study type:** Systematic review and meta-analysis **Size:** 40 RCTs (44 comparisons) with 3,277 pts 32 comparisons of protein vs. carbohydrate 12 comparisons of vegetable vs. animal protein 35 of the RCTs were conducted in normotensive persons (28 with SBP in the prehypertensive range) | **Inclusion criteria:**  
- RCT in humans  
- ≥18 y  
- Publication between January 1,1950 and April 1, 2011  
- No concurrent interventions  
- No more than 10% difference in calories, sodium, potassium, fiber between the treatment arms  
- Duration ≥1 wk  
**Exclusion criteria:** Missing key data | **Intervention:**  
- Protein intake  
- 1st meta-analysis: any source of protein, with a median protein supplementation dose of 40 g/d (20–66 g/d)  
- 2nd meta-analysis: specifically vegetable or animal protein  
**Comparator:**  
- 1st meta-analysis: carbohydrate  
- 2nd meta-analysis: vegetable or animal protein | **1° endpoint:**  
- 1st meta-analysis: There was a fairly consistent trend for a small BP lowering effect of protein compared to carbohydrate intake (86% of the trials). In a pooled analysis of the overall group (hypertensive and normotensive persons), the mean change in SBP was -1.76 (95% CI: -2.33– -1.20). In a subgroup of 15 trials in which none of the participants were receiving antihypertensive medication, the mean change in SBP was -1.95 (95% CI: -2.62– -1.29).  
- 2nd meta-analysis: For the comparison of vegetable vs. animal protein, there was no evidence of a difference in BP. In a pooled analysis of the overall group (hypertensive and normotensive pts) the mean change in SBP was -0.10 (95% CI: -2.31–2.11) mm Hg. In a subgroup of 8 trials in which none of the pts were receiving antihypertensive medication, the mean change in SBP was -0.55 (95% CI: -3.06–1.96). | - This is the most detailed and comprehensive review of the topic.  
- It provides strong evidence that protein supplementation results in a significant but modest reduction in BP and suggests that the effect size is similar following supplementation with protein from vegetables or animals. |
| Tielemans SM, et al., 2013 (71) 23514841 | **Aim:** Study the effect of protein intake on BP **Inclusion criteria**  
- RCTs, in "generally healthy adults" | **Intervention**  
- Protein intake | **1° Safety endpoint:** N/A |  
**1° endpoint:**  
- At baseline, the mean for age and SBP were 50 (range: 31–74) and 128 | **Findings consistent with experience in the meta-analysis by Rebholz et al.** |

</table>
| Aburto NJ, et al., 2013 (68) 23558164 | Study the effect of sodium reduction on BP | Systematic review and meta-analysis | Overall study included 36 trials (49 comparisons) conducted in 6,736 pts. Of these, 3,263 were nonhypertensive. The results in normotensives in this table are based on experience in 7 RCTs conducted in 3,067 normotensive pts. | - RCT in humans  
- Trial duration ≥4 wk  
- 24-h urinary sodium ≥40 mmol/d less in treatment compared to control group  
- No concurrent interventions  
- Not acutely ill | Sodium reduction | No sodium reduction | In pooled analysis, the overall change in SBP was -3.39 (95% CI: -4.31– -2.46) mm Hg. In the pts with HTN, the change was -4.06 (95% CI: -5.15– -2.96). In the normotensives, the change was -1.38 (95% CI: -2.74–0.02). | Safety endpoint: In the small number of relevant trials, there was no significant effect of sodium reduction on lipid levels (Total cholesterol, LDL-cholesterol, HDL-cholesterol, triglyceride levels; 11 trials) or on plasma (7 trials) or urinary catecholamine levels (2 trials). Experience in 4 trials (3 which could not be included in the meta-analysis) suggested a beneficial effect of sodium reduction on urinary protein excretion. |
| He FJ, et al., 2013 (75) 22437256 | Study the effect of sodium reduction on BP | Systematic review, meta-analysis and meta-regression analysis | Overall study included 34 trials (37 comparisons) conducted in 3,230 pts. | - RCTs  
- Healthy adults ≥18 y  
- Trial duration ≥4 wk  
- Sodium intake only difference between treatment and control group  
- 24-h urine sodium ≥40 mmol less in treatment compared to control | Sodium reduction | No sodium reduction | In an overall pooled analysis, the change for SBP was -4.18 (95% CI: -5.18– -3.18) mm Hg. In the trials of persons with HTN, the mean change was -5.39 (95% CI: -6.62– -4.15) mm Hg. In the trials conducted in normotensives, the change in SBP was -2.42 (95% CI: -3.56– -1.29) mm Hg.  
- In meta-regression analysis, change in 24-h urinary sodium was significantly associated with reduction in SBP (4.3 mm Hg for a 100 mmol reduction in 24-h urinary sodium). | Safety endpoint: In the small number of relevant trials, there was no significant effect of sodium reduction on lipid levels (Total cholesterol, LDL-cholesterol, HDL-cholesterol, triglyceride levels; 11 trials) or on plasma (7 trials) or urinary catecholamine levels (2 trials). Experience in 4 trials (3 which could not be included in the meta-analysis) suggested a beneficial effect of sodium reduction on urinary protein excretion.  
- The meta-regression results were consistent with a dose-response relationship in normotensive pts. |
pts. 12 of the RCTs (14 comparisons) were conducted in 2,240 normotensive pts.

Safety endpoint:
In the small number of relevant trials (which included both hypertensive and normotensive pts) that provided safety endpoint measurements (4–14 trials), there was no change in total, LDL- or HDL- cholesterol, or triglyceride levels. There were small significant increases in plasma renin activity, aldosterone, and noradrenaline levels but these were consistent with expected physiologic responses to sodium reduction.

Graudal NA, et al., 2012 (76) 22068710

Aim: Study the effect of sodium reduction on BP

Study type: Systematic review and meta-analysis

Size: Overall study included 167 trials. Of these, 71 RCTs were conducted in 5,577 normotensive pts, with the following characteristics:
- Median age: 27 y (13–67 y)
- Median trial duration: 7 d (4–1,100 d)
- 5,292 Whites (71 studies)
- 268 Blacks (7 studies)
- 215 Asians (3 studies)

Inclusion criteria:
- RCTs
- 24-h collections or estimates from ≥8 h collections of urinary sodium excretion

Exclusion criteria:
Systematic studies in unhealthy pts with diseases other than HTN

Intervention: Sodium reduction

Comparator: No sodium reduction

1° endpoint: The overall effect of sodium reduction was not presented.

A forest plot of 71 comparisons (from 61 trials) in the 4,919 normotensive whites assigned to sodium reduction compared to usual sodium intake identified a trend towards lower SBP in 50 (70%), no difference in 8 (11%), and higher SBP in 13 (19%). In a pooled analysis, sodium reduction compared to usual sodium intake in the normotensives yielded the following MDs in SBP:
- Whites: -1.27 (95% CI: -1.88– -0.66)
- Blacks: -4.02 (95% CI: -7.37– -0.68)
- Asians: -1.27 (95% CI: -3.07– -0.54)

A corresponding analysis in the hypertensives yielded the normotensives yielded the following MDs in SBP:
- Whites: -5.48 (95% CI: -6.53– -4.43)
- Blacks: -6.44 (95% CI: -8.85– -4.03)
- Asians: -10.21 (95% CI: -16.98– -3.44)

Safety endpoint: In the relevant trials (all cross-over studies and including

Heterogeneous group of trials that included many small studies of short duration in young persons.
- Overall finding of lower BP in those assigned to a reduced intake of dietary sodium, with an apparently greater effect in Blacks compared to Whites and Asians.
- The hormone changes in this meta-analysis likely reflect a physiologic response to sodium reduction, especially in studies of short duration and rapid changes in sodium intake. The increases in total cholesterol and triglyceride levels were not noted in the meta-analyses conducted by Aburto et al. and He et al.
comparisons in both hypertensive and normotensive participants) that provided safety endpoint measurements, significant increases in the standard MD for plasma renin activity (70 trials), aldosterone (51 trials), noradrenaline (31 trials), adrenaline (14 trials), and weighted MD for total cholesterol (24 trials), and triglyceride (18 trials) levels. There was no significant effect of sodium reduction on LDL-cholesterol (15 trials) and HDL-cholesterol (17 trials).

### DASH-Sodium Trial

**Sacks FM, et al., 2001 (77)**

- **Aim**: Study the effect of sodium reduction on BP
- **Study type**: Randomized, controlled crossover trial
- **Size**: Overall study based on 412 pts, of whom 243 were normotensive
- **Inclusion criteria**: Adults ≥22 y
- **Exclusion criteria**: Taking antihypertensive medication, heart disease, renal disease, poorly controlled hyperlipidemia or DM, DM requiring insulin, special dietary requirements, >14 drinks/wk
- **Intervention**: Feeding study in which pts were randomized to a DASH or control diet at 3 levels of assigned dietary sodium intake (High=210 mmol/d; Intermediate=100 mmol/d; Low=50 mmol/d)
- **Comparator**: Each pt served as their own control (crossover design)

1° endpoint:
- Reduced sodium intake resulted in a significant reduction in SBP, with a greater reduction during assignment to the Low compared to the Intermediate sodium intake diet. At every level of sodium intake, the achieved reduction in SBP was greater on the control group compared to the DASH diet and for Blacks compared to other pts.
- Reducing sodium intake from the high to intermediate level decreased SBP by 2.1 mm Hg (p<0.001) during the control diet and 1.3 mm Hg (p=0.03) during the DASH diet.
- Reducing sodium intake from the intermediate low level decreased SBP by a further 4.6 mm Hg (p<0.001) during the control diet and 1.7 mm Hg (p<0.01) during the DASH diet.

Safety endpoint: N/A

- This trial provides the best (direct) evidence for a dose-response treatment relationship between sodium intake and level of BP.
- It also suggests the relative effect of reduced sodium intake is greater in persons with a typical U.S. diet but the combination of sodium reduction and consumption of a DASH-type diet results in a lower level of BP than can be achieved with either dietary modification on its own.
- Consistent with other trials and meta-analyses, it suggests the effect of a reduced sodium intake is greater in Blacks compared to others, especially for those consuming a typical U.S. diet.

### TOHP II Trial (Sodium component)

**Kumanyika SK, et al., 2005 (78)**

- **Aim**: Study the effect of sodium reduction on BP and prevention of HTN.
- **Study type**: Randomized,
- **Inclusion criteria**: Healthy community-dwelling adults 30–54 y to BMI between 110% and 165% of desirable body weight
- **Intervention**: Behavior change intervention aimed at studying the effects of modest (25%–30%) reductions in dietary sodium intake during

1° endpoint:
- Compared to usual care, the sodium reduction group experienced a significant mean reduction of 51 mmol for 24-h urinary excretion and -2.9 (SD: 0.5) mm Hg (p<0.001) in SBP at 6 mo (-5.1 mm Hg in
- **Comparator**: N/A

- This was the largest trial of sodium reduction in HTN prevention and also provides the longest duration of follow.
- The assumptions for a main effects factorial analysis (independence of the
controlled factorial trial.

**Size:** 2,382 pts, of whom 594 were randomized to sodium reduction (alone) and 596 were randomized to usual care.

- Not taking BP-lowering medication
- Mean SBP <140 mm Hg and DBP 83–89 mm Hg

**Exclusion criteria:**
- Taking antihypertensive medication
- Heart disease, renal disease, poorly controlled hyperlipidemia or DM, DM requiring insulin, special dietary requirements, >14 drinks/wk.

**Comparator:** Usual care group

up to 48 mo (minimum 36 mo) of follow-up.

the sodium reduction group and -2.2 mm Hg in the usual care group).

- A progressive reduction in effect size for urinary sodium excretion and BP was noted over time, with mean for SBP at 18, 36 mo and termination of -2.0 (SD: 0.5) mm Hg (p<0.001), -1.2 (SD: 0.5) mm Hg (p=0.02), and -1.0 (SD: 0.5) mm Hg (p=0.5).

**Prevention of HTN**
- At 6 mo of follow-up the incidence of new onset HTN was 39% lower in the pts randomized to reduced dietary sodium intake compared to the usual care group (p=0.04).
- During more prolonged follow-up, the effect size decreased but remained significant after 48 mo of follow-up (14% reduction; p=0.04). Overall, the incidence of HTN was reduced by 18% (p=0.048).

**Safety endpoint:** N/A

TOHP Phase I
1992 (79)

**Aim:** Study the effect of sodium reduction on BP and prevention of HTN

**Study type:** Randomized, controlled factorial trial.

**Size:** Overall, 2,182 adults, with the 327 assigned to sodium reduction compared

**Inclusion criteria:**
- Community-dwelling adults 30–54 y
- Not on antihypertensive medication
- DBP 80-89 mm Hg
- Healthy

**Exclusion criteria:**
- Disease
- Inability to comply with the protocol

**Intervention:** Behavior change intervention

**Comparator:** Usual care

1° endpoint:
Change in DBP

2° endpoint:
Change in SBP

**Safety endpoint:**
CVD events, symptoms and general well being

• Significantly lower DBP (0.9 mm Hg; p<0.05) and SBP (1.7 mm Hg; p<0.01) in the sodium reduction group compared to usual care
• Few CVD events
• No difference in symptoms
• Significant improvement in general well-being at 6 and 18 mo (p<0.05)
Cook NR, et al., 2007 (80)  

**Aim:** Study the effect of sodium reduction on CVD morbidity and mortality.

**Study type:** 10–15 y post-trial follow-up of TOHP I and TOPH II pts that took advantage of the randomized trial design. Vital status was obtained for 100% of the pts and information on morbidity was obtained from 2,415 (77%) of the pts.

**Inclusion criteria:** Assigned to dietary sodium reduction or control in TOHP Phase I or TOHP Phase II.

**Exclusion criteria:** None

**Intervention:** Behavior change intervention aimed at studying the effects of modest (25%–30%) reductions in dietary sodium intake during TOHP Phase I or TOHP Phase II.

**Comparator:** No sodium reduction intervention.

**1° endpoint:**
- 200 CVD events and 77 deaths during follow-up
- Kaplan-Meier plots identified trends toward less morbidity and mortality in those who had been randomized to sodium reduction compared to usual care, with a consistent pattern for the TOHP I and TOHP II participants
- Risk of a CVD event was 30% lower (RR: 0.70; 95% CI: 0.53–0.94; p=0.018) among those randomized to sodium reduction compared to usual care, after adjustment for trial, clinic, age, race, sex, baseline weight and sodium excretion
- RR for total mortality was 0.80 (95% CI: 0.51–1.26).

**Safety endpoint:** N/A

Data Supplement 14. RCTs Studying the Effect of Nonpharmacologic Interventions on BP (Stress Reduction) (Section 6.2)

| Canter PH, et al., 2004 (81)  

**Aim:** Study the effect of transcendental meditation on BP  
**Study type:** Systematic review  
**Size:** | **Inclusion criteria:**  
- RCT in humans  
- Publication in any language until May 2004  
- No concurrent interventions | **Intervention:**  
- Use of transcendental meditation techniques as taught by Maharishi Mahesh Yogi  
- Practiced on a regular basis over an extended period | **1° endpoint:** Statistically significant reduction in SBP reported in 3 of 5 trials that provided such information.  
**1° Safety endpoint:** N/A | ● Only a handful of RCTs available from the large number of publications on this topic.  
● Trials had methodological weaknesses and were subject to potential bias due to the affiliation of authors to the transcendental meditation organization. |
6 RCTs with wide range of pts: young to elderly; healthy volunteers to Blacks with HTN.
- HTN: 2 trials
- High normal BP: 2 trials
- Normotensive: 1 trial
- Not stated: 1 trial
Sample sizes ranging from 34–156 pts
Follow-up from 2 mo–1 y

Exclusion criteria: N/A
Comparator: No treatment, sham, alternative treatment

- A few trials reported small reductions in SBP but clinical relevance of findings is unclear.
- Most of the trials were underpowered and could have missed a significant finding.
- The authors concluded that “there is at present insufficient good quality information to conclude whether or not transcendental meditation has a cumulative positive effect on BP”

### Study Description

**Aim:** Study the effect of different levels of sodium intake on BP during consumption of a DASH or usual U.S. diet

**Study type:**
- Multicenter RCT with 2 parallel diet arms (DASH diet or usual U.S. diet)
- Within each arm, randomized cross-over trial with 3 periods testing different levels of sodium intake (no washout)

**Size:** 412, with 59% (243) being normotensive

**Inclusion criteria:**
- Adults ≥22 y
- Average SBP between 120–159 mm Hg and average DBP between 80–95 mm Hg
- No use of antihypertensive medication

**Exclusion criteria:**
- Heart disease, renal insufficiency, poorly controlled hyperlipidemia or DM, DM requiring insulin, special dietary requirements, >14 alcoholic drinks /wk.

**Intervention:** 3 levels of dietary sodium while consuming a DASH or usual U.S. diet.
- High: 150 mmol (3,450 mg)/d
- Intermediate: 100 mmol (2,300 mg)/d
- Low: 50 mmol (1,150 mg)/d

The mean achieved levels of sodium during the high, intermediate and low sodium periods were 144, 107 and 67 mmol/d in the DASH diet group and 141, 106, and 64 mmol/d in the usual U.S. diet group.

**Comparator:** See description above

**1° endpoint:**
- At each level of sodium intake, SBP and DBP were lower during consumption of the DASH diet compared to the usual U.S. diet, the difference being greatest with high sodium intake and lowest with low sodium intake, with the mean SBP difference between the DASH and usual US diets during high, intermediate and low sodium intake being -5.9 (95% CI: -8.0– -3.7), -5.0 (95% CI: -7.6– -2.5), and -2.2 (95% CI: -4.4– -0.1). The corresponding differences for DBP were -2.9 (95% CI: -4.3– -1.5), -2.5 (95% CI: -4.1– -0.8), and -1.0 (95% CI: -2.5, 0.4).
- In both the DASH and usual U.S. diet arms, SBP and DBP were significantly lower during intermediate compared to high sodium intake, and during low compared to intermediate sodium intake, with the decrement being greater for the latter change.
- In comparison to consumption of a usual U.S. diet at the high level of

- Multicenter RCT with 2 parallel diet arms (DASH diet or usual U.S. diet)
- Within each arm, randomized cross-over trial with 3 periods testing different levels of sodium intake (no washout)
| **Size:** 412, with 59% (243) being normotensive |
| **Inclusion criteria:**
- Adults ≥22 y
- Average SBP between 120–159 mm Hg and average DBP between 80–95 mm Hg
- No use of antihypertensive medication |
| **Exclusion criteria:**
- Heart disease, renal insufficiency, poorly controlled hyperlipidemia or DM, DM requiring insulin, special dietary requirements, >14 alcoholic drinks /wk. |
| **Intervention:** 3 levels of dietary sodium while consuming a DASH or usual U.S. diet.
- High: 150 mmol (3,450 mg)/d
- Intermediate: 100 mmol (2,300 mg)/d
- Low: 50 mmol (1,150 mg)/d
| The mean achieved levels of sodium during the high, intermediate and low sodium periods were 144, 107 and 67 mmol/d in the DASH diet group and 141, 106, and 64 mmol/d in the usual U.S. diet group. |
| **Comparator:** See description above |
| **1° endpoint:**
- At each level of sodium intake, SBP and DBP were lower during consumption of the DASH diet compared to the usual U.S. diet, the difference being greatest with high sodium intake and lowest with low sodium intake, with the mean SBP difference between the DASH and usual US diets during high, intermediate and low sodium intake being -5.9 (95% CI: -8.0– -3.7), -5.0 (95% CI: -7.6– -2.5), and -2.2 (95% CI: -4.4– -0.1). The corresponding differences for DBP were -2.9 (95% CI: -4.3– -1.5), -2.5 (95% CI: -4.1– -0.8), and -1.0 (95% CI: -2.5, 0.4).
- In both the DASH and usual U.S. diet arms, SBP and DBP were significantly lower during intermediate compared to high sodium intake, and during low compared to intermediate sodium intake, with the decrement being greater for the latter change.
- In comparison to consumption of a usual U.S. diet at the high level of |

---

This trial provided additional documentation of the effectiveness of a DASH diet in lowering BP in normotensives (and hypertensives) and the complementary benefit of consuming a reduced intake of sodium.
### PREMIER

**Appel LJ, et al., 2003 (83) 12709466**

**Aim:** Study the effect of 2 behavioral interventions, aimed at dietary change, on BP

**Study type:**
- Multicenter RCT with 3 parallel arms:
  - Established
  - Established plus DASH diet
  - Advice only

**Size:**
- 810 adults, with 62% (506) normotensive. At baseline, mean age, BMI and SBP/DBP were 50 y, 33 kg/m², and 135/85 mm Hg, respectively.

**Duration:** 6 mo, with observations at 3 and 6 mo.

**Inclusion criteria:**
- Adults ≥25y
- Average SBP between 120–159 mm Hg and average DBP between 80–95 mm Hg
- No use of antihypertensive medication
- BMI between 18.5 and 45 kg/m²

**Exclusion criteria:**
- Regular use of drugs that affect BP
- Target organ damage or DM
- Use of weight-loss meds
- Hx CVD event
- HF, angina, cancer, within 2 y
- Consumption of >21 alcoholic drinks /wk
- Pregnancy, planned pregnancy, lactation

**Intervention:**
- Structured behavioral interventions that used an identical format (4 individual and 14 group sessions) to facilitate adoption of “established” dietary recommendations for reduction in BP or “established” plus the DASH diet. The “established” dietary recommendations used in PREMIER were a) weight loss in overweight participants, b) sodium reduction, increased physical activity, reduced alcohol intake in pts consuming alcohol.

**1° endpoint**
- Compared to control (advice only), SBP and DBP were significantly reduced with both active interventions but there was no significant difference in the effect size between the 2 active intervention groups. This was true for both the normotensive and hypertensive pts, with the effect size being larger in the hypertensive group. In the normotensives, the MD for change in SBP was identical for the “established” compared to “established plus DASH Diet” groups: -3.1 (95% CI: -5.1– -1.1) mm Hg

The corresponding changes for DBP were -1.6 (95% CI: -2.9– -0.2) for the “established” intervention group and -2.0 (95% CI: -3.4– -0.6) for the “established intervention plus DASH Diet” group.

**1° Safety endpoint:** Participants tended to report less symptoms during periods of reduced sodium intake, with a statistically significant reduction in reports of headache (p<0.05) consistent with prior experience in the TONE trial.

**This was an interesting trial which employed a behavior change approach to implement both active interventions.**

**The investigators goal was to determine the additive value of the DASH Diet in persons already following key elements of conventional (established) recommendations for nonpharmacologic intervention to lower BP.**

**The intervention approach in this trial was less effective in achieving weight loss and reduction in dietary sodium compared to the corresponding experience in the TOHP and TONE trials and the DASH Diet effects on intermediate variables (such as fruit and vegetable consumption) was less than that achieved in the DASH Diet feeding studies.**

**Despite the modest intervention effects, both SBP and DBP were significantly reduced with the conventional intervention approach (in normotensives as well as overall) and addition of the DASH diet did not have a
intervention goals in the “established” group, with a MDs of 3.8 kg (8.4 lbs) for body weight, 11.6 mmol (267 mg)/d for urinary sodium excretion, no change in physical activity (but better fitness), and no change in alcohol consumption (but very low alcohol consumption at baseline).

- Weight loss was somewhat greater in the “established” plus DASH diet group, with a MD of 4.8 kg (10.6 lbs) for body weight. This group also manifested expected effects of the DASH diet, with significantly higher urinary potassium and phosphorous levels, greater consumption of fruits and vegetables, dietary calcium, dairy products, and a lower consumption of total fat and saturated fat.

Comparator: Advice only

HTN was significantly less and the percent with optimal BP was higher in both active intervention groups compared to advice only. The difference between the 2 active intervention groups was not significant. In the normotensives, there was a nonsignificant trend towards less HTN and a significantly higher percent with optimal BP in both active intervention groups compared to advice only, with no significant difference for percent with optimal BP in the 2 active intervention groups.

1° Safety endpoint: N/A

There were some nonsignificant trends for slightly lower BP, less HTN, and more optimal BP in the “established plus DASH Diet” group compared to “established” group. The authors also cited use of the DASH Diet as a means to beneficially influence CVD risk factors in addition to BP.

Aim: Compare effects of 3 diets, each with a reduced intake of saturated fats, on BP and serum lipids

Inclusion criteria: • Adults ≥30 y • Average SBP between 120–159 mm Hg and

Intervention: • High protein with reduced fat/saturated fat content

1° endpoint Compared with the high carbohydrate diet, the high protein diet:

This clinical trial demonstrated that substituting either protein or monounsaturated fat in place of carbohydrate resulted in a small
### Study type:
- 2 center RCT
- 3 period crossover design
- Each 8 wk period was separated by a 2–4 wk wash-out phase

### Size: 161–164 included in analyses (191 pts randomized). 132 (80.5%) of the 164 included in the BP analyses were normotensive. Mean age and BMI were 54 y and 30.2 kg/m², respectively.

<table>

</thead>
<tbody>
<tr>
<td><strong>Study type:</strong></td>
<td>• Systematic review and meta-analysis • Cochrane Collaboration strategy</td>
</tr>
<tr>
<td><strong>Size:</strong> 5 trials (447 pts)</td>
<td></td>
</tr>
</tbody>
</table>

| **Inclusion criteria:**       | **Intervention:** Low-carbohydrate diet: maximum of 60 g/d carbohydrate |
|-------------------------------|• RCT • Adults ≥16 y • Low-carbohydrate diet and low-fat diet interventions • BMI ≥25 kg/m² • Follow-up ≥6 m |
| **Comparator:** Low-fat diet: maximum of 30% energy from fat |

| **Intervention:** Low-carbohydrate diet: maximum of 60 g/d carbohydrate |
|• Behavioral counselling that used identical format to that employed in the low carbohydrate group |

| • At 3, 6, and 12 mo, BP tended to be lower in the low-carbohydrate group but none of the differences in SBP or DBP were significant. • CRP was reduced in both diet groups but to a significantly greater extent in the low-carbohydrate group. • At 6 and 12 mo pts in the low carbohydrate group experienced a significant improvement in their 10-y Framingham CHD risk score. In contrast, there was no change in Framingham CHD risk in the low-fat diet group. |

| **1° Safety endpoint:** No serious side effects noted |

| **1° Safety endpoint:** At 6 mo, the low-carbohydrate diet pts, compared to the low-fat diet participants, had a mean reduction in body weight that was greater by -3.3 (95% CI: -5.3–-1.4) kg, and a more favorable profile for HDL-cholesterol and triglyceride levels. In contrast, the profile for total-cholesterol and HDL-cholesterol was more favorable in those assigned to a low-fat diet. The profile for SBP tended to be better in the low carbohydrate diet pts but the differences were not significant: MD at 6 mo: -2.4 (95% CI: -4.9–0.1) mm Hg. |

| **1° Safety endpoint:** N/A |

<p>| • This systematic review/meta-analysis tends to suggest low-carbohydrate diets are somewhat more effective in reducing body weight compared to the traditionally recommended low-fat diets. • Although the BP differences were not significant they would probably have reached a conventional level of significance had subsequent clinical trials (including the Bazzano et al. trial) been included in the analysis. |</p>

<td>The percentage of pts with controlled BP increased in all 3 intervention groups (p-value for within-group changes: p&lt;0.001).</td>
<td>Overall, both the traditional Mediterranean diet and a low-fat diet exerted beneficial effects on BP and could be part of advice to pts for controlling BP.</td>
</tr>
</tbody>
</table>
**Study type:** RCT, single-blinded, in Spanish primary healthcare centers  

**Size:** 7,447 men (55–80 y) and women (60–80 y) at high risk for CVD.  

- DM or at least 3 major CVD risk factors (smoking, HTN, elevated LDL cholesterol, low HDL, overweight/obese, family history of early CHD)  

**Exclusion criteria:** Do not meet criteria listed above  

The control group received education on following a low-fat diet, while the groups on Mediterranean diets received nutritional education and also free foods; either extra virgin olive oil, or nuts.  

**Comparator:** Lower fat diet  

Allocated to either of the 2 Mediterranean diet groups had significantly lower DBP than the pts in the control group (-1.53 mm Hg (95% CI: -2.01 – -1.04) for the Mediterranean diet supplemented with extra virgin olive oil, and -0.65 mm Hg (95% CI: -1.15 – -0.15) mm Hg for the Mediterranean diet supplemented with nuts). No between-group differences in changes of SBP were seen.  

- However, lower values of DBP were noted in the 2 groups following the Mediterranean diet with extra virgin olive oil or with nuts than in the control group.

### Data Supplement 16. RCTs and Meta-analysis RCTs Studying the Effect of Nonpharmacologic Interventions on BP (Alcohol Reduction) (Section 6.2)

</thead>
</table>
| Xin X, et al., 2001 (90) 11711507     | **Aim:** Study the effect of alcohol reduction on BP  
**Study type:** Systematic review and meta-analysis  
**Size:**  
- 15 RCTs (25 comparisons) with 2,234 pts.  
- 6 trials were conducted in normotensives (269 pts with a mean age ranging from 26.5–45.5 y). Average | **Inclusion criteria:**  
- RCT in humans  
- Publication between 1966-1999  
- Duration ≥1 wk  
- Only pts regularly consuming alcohol  
- Only difference between the comparison groups was alcohol intake  

**Exclusion criteria:** Comparison of different doses of alcohol intake | **Intervention:** Reduction in alcohol consumption. In most trials this was achieved by randomization to “light” alcohol but some RCT were based on a behavioral intervention aimed at reducing the number of drinks consumed.  

**Comparator:** Usual consumption of alcohol | **1° endpoint:**  
- Overall, alcohol reduction was associated with a significant reduction in mean SBP of -3.31 (95% CI: -4.10 – -2.52) and DBP of -2.04 (95% CI: -2.58 – -1.49).  

- In the subgroup of 7 RCTs in persons with HTN, the mean changes in SBP and DBP were -3.9 (95% CI: -5.04 – -2.76) and -2.41 (95% CI: -3.25 – -1.57).  

- In the subgroup of 6 RCTs in normotensives the corresponding changes in SBP and DBP were -3.5 (95% CI: -4.61 – -2.51) and -1.80 (95% CI: -3.03 – -0.58).  

- This is the most recent meta-analysis of this topic. Although this meta-analysis reports % reduction in alcohol intake, most trials aimed at reducing the number of alcoholic drinks consumed achieved a reduction of about 3 drinks/d.  

- The intervention results were consistent with the relationship alcohol and BP in observational epidemiology – about a 1 mm Hg higher SBP per alcoholic drink consumed. In observational studies, type of alcohol does not seem to matter and at lower levels of alcohol consumption (<1 standard size alcoholic drink per day in women and <2 in men) there does not

<td>N/A</td>
</tr>
</tbody>
</table>

- In a meta-regression analysis, a dose-response was noted between % reduction in alcohol consumption and mean reduction in BP.
- The relationship between alcohol consumption and BP is predictable and consistent in observational and RCT studies. However, the relationship between alcohol consumption and CVD is more complex as alcohol is associated with an apparently beneficial effect on CVD risk, possibly mediated by an increase in HDL-cholesterol.
- Pregnant women, pts with HTN and those at risk of a drinking problem should not drink alcohol. Established light drinkers (<2 standard drinks/d in men and <1/d in women) who are normotensive are in a favorable risk category for CVD.

**Interventions:** Including reduced alcohol intake, for treatment of HTN. **Study type:** 1 of 10 meta-analyses. **Size:** 4 trials which collectively studied 305 pts
- SBP ≥140 mm Hg and/or DBP ≥85 mm Hg
- ≥8 wk duration
- BP outcome

**Exclusion criteria:**
- 2º HTN or renal disease
- Pregnant women
- Change in BP meds during trial

**Comparator:** Usual care

**DBP:** -3.2 (-5.0 — -1.4)

**Safety endpoint:** N/A

**Wallace P, et al., 1988 (93) 3052668**

**Aim:** Study effectiveness of general practitioner advice to reduce heavy drinking.

**Study type:** RCT

**Size:** 909 adults (641 men and 268 women)

**Inclusion criteria:** Heavy drinking during wk prior to screening interview.

**Exclusion criteria:** None mentioned

**Intervention:** Physician counselling aimed at reduced consumption of alcohol.

**Comparator:** Usual care

**Endpoints:**
- 1° outcome was reduction in percent with heavy consumption of alcohol (mean net change=46%). Liver enzymes and BP also measured at 6 and 12 mo.
- Pretreatment SBP/DBP=133.5/79.9 mm Hg.
- Net reduction SBP=−2.12 (95% CI: -4.19– -0.00)

**Safety endpoint:** N/A

**Lang T, et al., 1995 (94) 8596098**

**Aim:** Worksite study of reduced alcohol intake effect on BP in heavy drinkers with HTN.

**Study type:** RCT

**Size:** 14 site physicians; 129 adults (95% men)

**Inclusion criteria:** Heavy drinking (documented by history and liver enzyme elevation).

- HTN (SBP/DBP >140/90 mm Hg)
- 2º HTN
- Severe liver disease
- Planned move/retirement.

**Exclusion criteria:**

- Baseline DBP=5.5 (p<0.05). When 5 sites with <5 workers/site were excluded, the net change in SBP=−7.3 mm Hg (p<0.01).
- At 2 y, the net change in SBP=−6.6 (p<0.05).

**Intervention:** Physician and worker counselling aimed at reduced consumption of alcohol.

**Comparator:** Usual care.

**Duration:** Follow-up visits at 1, 3, 6, and 18 mo.

**Endpoints:**
- Baseline SBP/DBP=162.5/98.0. Although all of the workers had HTN, only about 20% were being treated with antihypertensive medications at baseline.
- At 1 y, the net change in SBP=−5.5 (p<0.05). When 5 sites with <5 workers/site were excluded, the net change in SBP=−7.3 mm Hg (p<0.01).
- At 2 y, the net change in SBP=−6.6 (p<0.05).

**Safety endpoint:** N/A

**● The goal was to blind those conducting the outcome assessment to treatment assignment but by 6 mo assignment was known in 20-30% of the participants.**

**● A reduction in SBP was noted despite use of a modest intervention.**

**● Behavioral intervention state of the art for its time**

**● Careful measurements of BP using Hawksley RZ sphygomanometer.**

**● Main analyses do not seem to have accounted for cluster design.**
| **Aim:** Study the effect of reduced alcohol intake on BP. | **Inclusion criteria:**  
- RCT in adult humans  
- Publication on or before July 13, 2016.  
- Full text articles.  
- Change in alcohol intake for ≥1 wk | **Intervention:** Reduction in alcohol consumption. Strategy varied from controlled inpatient administration to randomization to “light” alcohol to pragmatic primary care trials with counselling to reduce alcohol intake. | **Safety endpoint:** N/A |
|---|---|---|---|
| **Study type:** Systematic review and meta-analysis. | **Design:**  
- 15 parallel-arm trials  
- 21 crossover trials | **Duration:** Follow-up from 1 wk to 2 y (median 4 wk). | **1st endpoint:**  
- Overall, alcohol reduction was associated with a significant reduction in mean SBP of -3.31 (95% CI: -4.10– -2.52) and DBP of -2.04 (95% CI: -2.58– -1.49).  
- In the subgroup of 7 RCTs in persons with HTN, the mean changes in SBP and DBP were SBP: -3.13 (95% CI: -3.93– -2.32) DBP: -2.00 (95% CI: -2.65– -1.35).  
- In meta-regression analysis, there was a strong relationship between the extent of BP reduction and change in BP, with no reduction in BP for those consuming 2 or less drinks at baseline but increasing reductions in BP for those with progressively higher intakes of alcohol at baseline. For instance, in those consuming ≥6 drinks/day and reducing their alcohol intake by approximately 50%, the estimated reduction in SBP and DBP were: SBP: -5.5 (95% CI: -6.70– -4.30)  
DBP: -3.97 (95% CI: -4.70– -3.25). Similar patterns of the effect of baseline alcohol intake on treatment effect were noted for a variety of subgroups. | **1st Safety endpoint:** N/A |
| **Size:** 36 RCT with 2865 participants. | **Setting:**  
- 13 in hypertension  
- 13 in normotension  
- 12 HTN and NT  
- Only 3 trials presented data for women. |  | N/A |

</thead>
</table>
| Van Mierlo LA, et al., 2006 (95) 16673011 | **Aim:** Study the effect of calcium supplementation on BP  
**Study type:** Systematic review and meta-analysis  
**Size:**  
- 40 RCTs with 2,492 pts.  
- 27 RCTs in pts <140/90 mm Hg (n=1,728)  
- Follow-up varied from 3–208 wk (median=8.5 wk)  
- Age range 11–77 y (mean=43.7 y)  
**Inclusion criteria:**  
- RCT in humans  
- Publication between 1996 and 2003  
- Nonpregnant normotensive pts or hypertensive pts  
- Only difference between the comparison groups was magnesium intake  
- Follow-up ≥2 wk  
**Exclusion criteria:** Study pts having renal disease or hyperparathyroidism  
**Intervention:** Increased calcium intake, with a range from 355–2,000 mg/d (mean=1,200 mg/d; median=1,055 mg/d), primarily as a gluconate or carbonate salt.  
**Comparator:** Placebo or usual intake – 32 double-blind.  
**1° endpoint:**  
- Overall, increased calcium intake was associated with a significant reduction in mean SBP of -1.86 (95% CI: -2.91– -0.81) and DBP of -0.99 (95% CI: -1.61– -0.37).  
- The reduction was slightly less but still significant in the subset of 32 double-blind trials, with a mean SBP of -1.67 (95% CI: -2.87– -0.47) and DBP of -0.93 (95% CI: -1.64– -0.22).  
- There was no significant difference between the effect size in those with a baseline BP ≥ or<140/90 mm Hg.  
- The mean change in SBP and DBP for those with a baseline BP ≥140/90 mm Hg (23 comparisons) was -2.17 (95% CI: -3.78– -0.55) and -0.95 (95% CI: -1.89– -0.01), respectively.  
- The mean in SBP and DBP for those with a baseline BP <140/90 mm Hg was -1.67 (95% CI: -3.01– -0.27) and -1.02 (95% CI: -1.85– -0.19) mm Hg, respectively.  
- The authors reported slightly larger effect sizes in those with a lower initial calcium intake, in trials that employed a dietary - This is the most recent SR/MA on this topic to include RCT conducted in both normotensive and hypertensive pts. The authors interpreted their results as being consistent with a beneficial effect of calcium supplementation on BP, with about a 2 mm Hg reduction in SBP for a 1 g increase in calcium intake. This is slighter larger effect size than noted in several earlier meta-analyses.  
- A subsequent Cochrane Collaboration meta-analysis was confined to 13 RCT in 485 adults (≥18 y) with HTN studied for ≥8 wk (Dickinson HO et al. Cochrane Database of Systematic Reviews. 2006; CD004639). The authors noted a significant reduction in mean of -2.5 (95% CI: -4.5– -0.6) for SBP but a more modest insignificant change of -0.8 (95% CI: -2.1– 0.4) for DBP. Due to the poor quality of the RCT and heterogeneity of the results, the authors concluded the reduction in SBP was likely an artifact due to bias.  
- Although not included in most meta-analyses, calcium supplementation has been effective as a treatment in pregnant women at risk for pre-eclampsia.  
- Several of the meta-analyses (including the 1 by van Mierlo et al) have suggested a bigger effect size in persons with a lower intake of calcium at baseline and in trials that utilized a dietary intervention. |
### 1° Safety endpoint: N/A

- Most of the trials were of short duration and did not (have the capacity) report on potential adverse effects such renal stones.
- In addition to being small, several trials were of uncertain quality.
- Overall, RCT experience provides limited and inconsistent evidence from trials of variable quality in support of calcium supplementation for prevention (or treatment) of HTN. Better evidence supports the role of calcium supplements, in conjunction with vitamin D, in strengthening bone density.

### Data Supplement 18. RCTs and Meta-analyses RCTs Studying the Effect of Nonpharmacologic Interventions on BP (Physical Activity) (Section 6.2)

<table>

| Whelton SP, et al., 2002 (96) 11926784 | **Aim:** Study the effect of aerobic exercise on BP  
**Study type:** Systematic review and meta-analysis  
**Size:** 38 reports (54 comparisons) with 2,419 pts; 27 of the comparisons were conducted in normotensive pts  
**Inclusion criteria:**  
- English language publication between 1966–2001  
- RCT in adults ≥18 y  
- Duration ≥2 wk  
- No concurrent interventions  
**Exclusion criteria:** Missing BP data |  
**Intervention:** Aerobic exercise  
**Comparator:** No exercise prescribed |  
**1° endpoint:**  
- For the overall group, a pooled analysis of experience in 53 trials identified a mean net change in SBP of -3.84 (95% CI: -4.97– -2.72). In subgroup analysis, the effect was noted in different ethnic groups, in trials that employed different designs, durations, and sample sizes, in trials with obese, overweight or normal weight pts, and in trials that employed different types, intensity levels, and duration of aerobic exercise.  
- In the subgroup of 15 trials in hypertensives, the mean net change in SBP was -4.94 (95% CI: -7.17– -2.70).  
- This meta-analysis provides the most comprehensive analysis of the effect of aerobic exercise on BP and provides strong evidence in support of aerobic exercise as an intervention to lower BP in normotensives.  
- Recognizing this, many of the trials were small and of short duration. |
### Cornelissen VA, et al., 2013 (97) 23525435

**Aim:** Study the effect of different types of physical activity on BP  
- Dynamic aerobic endurance  
- Resistance training  
- Dynamic  
- Static (Isometric)

**Study type:** Systematic review and meta-analysis

**Size:** Overall, 93 studies (>5,000 pts)  
- 59 Dynamic Aerobic Endurance studies  
- 13 Dynamic Resistance Training studies  
- 5 Combined Dynamic Aerobic and Resistance training  
- 4 Static (Isometric) Resistance  
- 12 Different interventions within 1 trial

**Inclusion criteria:**  
- Parallel arm RCTs  
- Adults≥18 y  
- Peer reviewed journals up to February 2012  
- Trial duration ≥4 wk

**Exclusion criteria:** Inadequate reporting of the data

**Intervention:** Physical activity  
**Comparator:** No prescription of physical activity

**Safety endpoint:** N/A

- In the subgroup of 27 trials conducted in normotensives, the mean net change in SBP was -4.04 (95% CI: -5.32– -2.75).

### Rossi AM, et al., 2013 (98) 23541664

**Aim:** Study the effect of resistance exercise on BP

**Study type:** Systematic review and meta-analysis

**Inclusion criteria:**  
- RCTs in adults (≥18 y)  
- BP-lowering 1° outcome

**Intervention:** Dynamic resistance training but overall reporting of the details was poor.

**Safety endpoint:** N/A

- Most recent in a series of progressively updated publications from Dr. Cornelissen and her colleagues.  
- The findings suggest a beneficial effect of all forms of physical activity on BP, with a disproportionately large effect of resistance training on BP.  
- Many of the available RCTs have been small, of short duration, and of uncertain quality.
### Garcia-Hermosa A, et al., 2013 (99) 23786645

**Aim**: Study the effect of exercise on BP in obese children.  

**Study type**: Systematic review and meta-analysis.  

**Size**: 9 RCTs (410 pts).  

**Inclusion criteria**:  
- Children ≤14 y with obesity  
- RCT  
- Duration ≥8 wk  
- 1° outcome: change in BP  

**Exclusion criteria**: Concomitant intervention  

**Intervention**: Physical activity, principally aerobic exercise.  

**Comparator**: No physical exercise, nutrition, education, or dietary restriction intervention  

**1° endpoint**: Change in SBP: In pooled analysis, mean change in SBP was -0.4 (95% CI: -0.66 – -0.24).  

**Safety endpoint**: N/A  

- This meta-analysis focused specifically on the effect of physical activity on BP in children with obesity. Although it is not stated explicitly, it seems likely that all of the participants were normotensive and not receiving medication that could influence level of BP.  
- The findings are consistent with other meta-analyses of the effect of physical activity on BP.  
- Only limited information regarding study details is provided in this publication. The interventions were heterogeneous in type, duration, and quality.

### Carlson DJ, et al., 2014 (100) 24582191

**Aim**: Study the effect of physical activity on BP in children with obesity.  

**Study type**: Systematic review and meta-analysis.  

**Size**: 9 RCTs (223 pts: 127 intervention and 96 controls): 6 were conducted in normotensives.  

**Inclusion criteria**:  
- Adults ≥18 y  
- RCT, including cross-over trials.  
- Duration ≥4 wk  
- Published in a peer reviewed journal between January 1, 1966 and July 31, 2013  

**Exclusion criteria**: Studies that employed any intervention other  

**Intervention**: Pure isometric exercise.  

**Comparator**: Use of a control group was a requirement but no additional specific information provided.  

**1° endpoint**:  
- In the overall pooled analysis (hypertensive and normotensive trials), mean change in SBP was -6.77 (95% CI: -7.93 – -5.62) mm Hg.  
- In the subgroup of 3 trials with hypertensive pts (all on antihypertensive medication), the mean change in SBP was -4.31 (95% CI: -6.42 – -2.21) mm Hg.  
- In the subgroup of 6 trials with normotensive pts, the mean change in SBP was -7.83 (95% CI: -9.21 – -6.45) mm Hg.  

- This study provides information regarding the effect of pure isometric exercise interventions on BP in adults.  
- The BP reductions reported in this meta-analysis are surprisingly large but the overall effect pattern is quite consistent with other meta-analyses of isometric exercise.
**Cornelissen VA, et al., 2011 (101) 21896934**

**Aim:** Study the effect of resistance training on BP.

**Study type:** Meta-analysis

**Size:** 28 randomized, controlled trials, involving 33 study groups and 1,012 pts.

**Inclusion criteria:**
- Adults ≥18 y
- RCT, including cross-over trials.
- Duration ≥4 wk
- Published in a peer reviewed journal up to June 2010

**Exclusion criteria:** Interventions other than pure isometric exercise (e.g., dynamic resistance)

**Intervention:** Resistance training, including isometric and dynamic modalities.

**Comparator:** Use of a control group was a requirement but no additional specific information provided.

**1° endpoint:** Resistance training induced a significant SBP/DBP reduction in 28 normotensive or prehypertensive study groups of -3.9 (-6.4, -1.2)/-3.9 (-5.6, -2.2) mm Hg. In the 5 hypertensive study groups, the change in mean SBP/DBP was -4.1 (95% CI: -0.63–1.4)/-1.5 (95% CI: -3.4–0.40) mm Hg. When the study groups were divided according to the mode of training, isometric handgrip training in 3 groups resulted in a larger decrease in SBP/DBP (-13.5 [95% CI: -16.5– -10.5]/-6.1 [95% CI: -8.3– -3.9] mm Hg) than dynamic resistance training in 30 groups (-2.8 [95% CI: -4.3– -1.3]/-2.7 [95% CI: -3.8– -1.7] mm Hg).

**Safety endpoint:** N/A

**Kass L, et al., 2012 (102) 22318649**

**Aim:** Study the effect of magnesium supplementation on BP

**Study type:** Systematic review and meta-analysis

**Inclusion criteria:**
- RCT in humans
- Parallel or cross-over design
- Publication before July 2010
- Adults ≥18 y
- Only difference between the

**Intervention:** Increased magnesium intake, with a range in elemental magnesium of 120 to 973 mg/d and a mean of 410 mg/d.

**Comparator:** Placebo or usual intake

**1° endpoint:** Overall, increased magnesium intake was associated with a small nonsignificant reduction in mean SBP of -0.32 (95% CI: -0.41– -0.23) and DBP of -0.36 (95% CI: -0.44– -0.27).

**Safety endpoint:** N/A

• This meta-analysis supports the BP-lowering potential of dynamic resistance training and isometric handgrip training.
• Results further suggest that isometric handgrip training may be more effective for reducing BP than dynamic resistance training.
• However, given the small amount of isometric studies available, additional studies are warranted to confirm this finding.
### Size
22 RCTs (23 comparisons) with 1,173 pts.

Data for RCTs conducted in normotensive pts were not presented. However, most RCTs were conducted in normotensives and only 6 of the RCTs included some (or all) pts who were being treated with antihypertensive medication. Overall mean age was ~50 y. Follow-up varied from 3–24 wk, with a mean of 11.3 wk.

### Comparison groups
comparison groups was magnesium intake

### Exclusion criteria
Comparison of different doses of alcohol intake

- Forest plots revealed considerable heterogeneity in effect size.
- The authors reported slightly larger effect sizes in subgroup analysis of cross-over RCT and RCT that employed a dose of magnesium >370 mg/d.

### 1° Safety endpoint
N/A

HTN et al (Am J Hypert. 2002;15:691-696) magnesium supplementation resulted in small mean NS reductions of -0.6 (95% CI: -2.2–1.0) mm Hg in SBP and -0.8 (95% CI: -1.9–0.4) in DBP. In meta-regression analysis, there was an apparent dose-response with SBP and DBP reductions of -4.3 (95% CI: -6.3–2.2) and -2.3 (95% CI: -4.9–0) mm Hg for each 10 mmol/d higher level of magnesium intake.

- A Cochrane systematic review/meta-analysis of magnesium supplementation for treatment of HTN in adults (Dickinson HO et al. Cochrane Database Systematic Review 2006: CD 004640) included 12 RCT (n=545) with follow-up of 8–26 wk. Overall, mean SBP and DBP were reduced by -1.3 (95% CI: -4.0–1.5) and -2.2 (95% CI: -3.4–0.9) mm Hg, respectively. The authors noted the studies were of poor quality, with considerable heterogeneity, and felt the results were likely biased.
- Some authors have suggested there may be a greater BP effect when the intervention is by means of diet change but there is insufficient RCT evidence to support this position.
- Magnesium sulfate is the drug of choice for prevention of seizures in the pre-eclamptic woman, or prevention of recurrence of seizures in the eclamptic woman, as demonstrated in RCT and a 2010 Cochrane review (Duley L et al. Cochrane Database of Systematic Reviews. CD000127, 2010).
- Overall, RCT experience provides insufficient evidence to recommend oral
magnesium supplementation as a means to prevent (or treat) HTN.

### Data Supplement 20. RCTs Studying the Effect of Nonpharmacologic Interventions on BP (Weight Loss) (Section 6.2)

| Neter JE, et al., 2003 (103) **12975389** | **Aim**: Study the effect of weight loss on BP  
**Study type**: Systematic review and meta-analysis  
**Size**: 25 RCTs (34 comparisons) with 4,874 pts; 17 of the comparisons were conducted in normotensive pts | **Inclusion criteria**:  
- RCT in humans  
- English language publication between 1966–2002  
- Nonpharmacologic intervention  
**Exclusion criteria**:  
- Duration <8 wk  
- Missing data  
- Objective not weight loss  
- Concomitant intervention(s) | **Intervention**: Weight loss (calorie reduction, physical activity, or combination of both)  
**Comparator**: No weight loss prescription | **1° endpoint**:  
- For the overall group, mean baseline body weight was 88.3 kg and mean change in body weight following the application of the weight loss intervention was -5.1 (95% CI: -6.03–-4.25) kg. This represents a mean percent change of -5.8%.  
- There was strong evidence for a BP lowering effect of weight loss on BP, overall and in normotensive subgroup. In the normotensive group, the mean for change in SBP was 4.08 (95% CI: -6.01–-2.16).  
- Overall, a 1 kg reduction in body weight was associated with a mean change in SBP of -1.05 (95% CI: -1.43–-0.66) mm Hg. | **Substantial evidence for a reduction in BP, overall and in normotensives.**  
**With the exception of the mean (95% CI) changes in BP, this paper provides limited data for the normotensive group** |
| Ho M, et al., 2012 (104) **23166346** | **Aim**: Study the effect of lifestyle weight loss interventions in obese/overweight children on weight  
**Inclusion criteria**:  
- RCTs, in obese/overweight children and adolescents ≤ 18 y | **Intervention**: Lifestyle weight loss program with a dietary component  
**Comparator**: No treatment, usual care or | **1° endpoint**: Pooled experience in the 7 RCTs with BP experience identified a significant reduction in mean SBP of -3.40 (95% CI: -5.19–-1.61). The pooled SBP MD was -3.72 (95% CI: -4.74–-2.69) in the 3 RCTs with a duration >1 y | **Findings in children are consistent with experience in adult normotensives and with experience in hypertensive pts.** |

### TONE (Weight Loss component)
Whelton PK, et al., 1998 (3)

**Aim:** Study the effect of weight loss on BP and need for antihypertensive drug therapy

**Study type:** RCT, factorial design

**Size:** 585 (obese) participants

**Inclusion criteria:**
- Community-dwelling adults 60-80 y
- SBP <145 mm Hg and DBP <85 mm Hg on 1 antihypertensive medication

**Exclusion criteria:**
- Heart attack or stroke within 6 mo
- Current angina, HF, insulin-dependent DM
- Inability to comply with protocol

**Intervention:** Behavior change intervention (combination of diet change and physical activity)

**Comparator:** Usual care, with similar level of contact compared to active intervention group

1° **endpoint:** Recurrence of HTN following withdrawal of antihypertensive medication (or CVD event)

2° **endpoint:** BP (while still on antihypertensive medication prior to tapering of medication)

**Safety endpoint:** CVD events, symptoms (including headaches), dietary composition

- Significant reduction in SBP prior to withdrawal of antihypertensive medication (mean±standard error=−4.0±1.3 mm Hg)
- 1° outcome significantly less common in weight loss group compared to usual care – Rel. HR: 0.70; 95% CI: 0.57–0.87; p<0.001
- No overt evidence for adverse effects of intervention

### TOHP, Phase I (Weight Loss component)
1992 (4)

**Aim:** Study the effect of weight loss on BP and prevention of HTN

**Inclusion criteria:**
- Community-dwelling adults 30–54 y

**Intervention:** Behavior change intervention (combination of diet change and physical activity)

1° **endpoint:** Change in DBP

2° **endpoint:** Change in SBP

- Significantly lower DBP (2.3 mm Hg; p<0.01) and SBP (2.9 mm Hg; p<0.01) in the weight loss group compared to usual care
- Few CVD events
**Study type:** Randomized, controlled factorial trial.

**Size:** Overall, 2,182 adults, with the 308 assigned to weight loss compared to 256 usual care controls.

**Exclusion criteria:**
- Not on antihypertensive medication
- DBP 80-89 mm Hg
- Healthy

**Comparator:** Usual care

**Safety endpoint:** CVD events, symptoms and general and well-being

- No difference in symptoms
- Significant improvement in general well-being at 6 and 18 mo

</table>
| LIFE Devereux RB, et al., 2004 (108) 15547162 | Study type: Sub-study of pts with HTN and ECG LVH Size: 941 | Inclusion criteria:  • 55–80 y  • BP 160–200/95–115 mm Hg  • No MI or stroke within 6 mo  • Had echo  • Did not require treatment with BB, ACE or AT-1 antagonist for other reasons | 1<sup>st</sup> endpoint: Change in LV mass assessed by echo and change in BP in relation to CVD events  
Results:  
• Composite endpoint of CV death, MI, or stroke reached in 104 in 4.8 y of follow-up  
• Reduction in 1<sup>st</sup> endpoint per SD reduction in LV mass independent of BP change OR: 0.74 (95% CI: 0.6–0.91; p=0.003)  
• Reductions for each composite endpoint component and total mortality were also significant; results independent of change in ECG LVH | Reduction in LV mass by echo independently related to CVD outcomes |
| CARDIA Armstrong AC, et al., 2014 (109) 24507735 | Study type: Observational study of population-based cohorts | Inclusion criteria: African American and white men and women stratified by education (above/below high school) 18–30 y at study start and followed for over 20 y; previously healthy | 1<sup>st</sup> endpoint: Composite of hard CVD events  
Results:  
• LV mass indexed to body surface area or to height predicted CV events independently of the Framingham risk score (HR: 1.21; 95% CI: 1.05–1.39; p<0.007) | LV mass measured at age 18–30 y leads to modest risk reclassification later in life  
Low number of events limits generalizability |
### ARIC
Okwuosa TM, et al., 2015 (110)  
25497261

**Study type:** Observational study of population-based cohorts  
**Size:** 14,489

**Inclusion criteria:** African American and white men and women population-based cohort mean age 54.7 ± 5.7 y at study start and followed for over 25 y; previously healthy

**1° endpoint:** Pooled cohort CV events and 10-y Framingham CVD events

**Results:**  
- 792 (5.5%) 10-y Pooled Cohort CV events and 690 (4.8%) 10-y Framingham CHD events.
- LVH was associated with CVD events (HR: 1.62; 95% CI: 1.38–1.90) and CHD events (HR: 1.56; 95% CIL 1.32–1.86).
- LVH by ECG did not significantly reclassify or improve C statistic compared with Framingham risk score (C statistics 0.767/0.719; net reclassification index =0.001 [p=not significant]), compared with (C statistics 0.770/0.718), respectively.

**Summary:** ECG LVH does not improve risk reclassification

### MESA
Zalawadiya SK, et al., 2015 (111)  
24699336

**Study type:** Observational study of population-based cohorts  
**Size:** 4,921

**Inclusion criteria:** Multi-ethnic cohort of men and women followed for a mean follow-up of 4.5 y

**1° endpoint:** Hard CVD endpoints

**Results:** MRI calculated LVH (indexed to BSA or height; >95th percentile) predicted hard CVD events (LVH-BSA: HR: 2.36; 95% CI: 1.37–4.04; p=0.002; LVH-height [1.7]: HR: 1.95; 95% CI: 1.17–3.26; p=0.01), but did not improve risk reclassification beyond conventional risk factors

**Summary:** Though LVH predicted events it did not improve risk reclassification

</tbody>
</table>

- Benefit for CVD not different for more intensive and less intensive targets in intensive group
  - <140 or <150 mm Hg: 0.76 (95% CI: 0.60–0.97)
  - <120–<130 mm Hg: 0.91 (95% CI: 0.84–1.00)
  - p-hetero: 0.06

- Absolute benefits were proportional to absolute risk.
- For trials in which all pts had vascular disease, renal disease, or DM at baseline, the average control group rate of major vascular events was 2.9% per y compared with 0.9% per y in other trials, and the numbers needed to treat were 94 (95% CI: 44–782) in these trials vs. 186 (95% CI: 107–708) in all other trials.
- Increase in severe hypotension: 0.3% vs. 0.1% per person y OR: 2.68 (95% CI: 1.21–5.89)
### Study type:
Meta-analysis of RCTs

**Size:** 123 studies with 613,815 pts

**Exclusion criteria:** <1,000 pt-y of follow-up in each treatment group.

- **HF RR:** 0.72 (95% CI: 0.67–0.78)
- **Total deaths RR:** 0.87 (95% CI: 0.84–0.91)

**Other results:**
- Benefit for CVD and other endpoints not different by baseline SBP, including <130 mm Hg
- **CVD:** 0.63; 95% CI: 0.50–0.80; p=0.22
- **CHD:** 0.55; 95% CI: 0.42–0.72; p=0.93
- **Stroke:** 0.65; 95% CI: 0.27–1.57; p=0.38
- **HF:** 0.83; 95% CI: 0.41–1.70; p=0.27
- **Total deaths:** 0.53; 95% CI: 0.37–0.76; p=0.79

- More precision around estimates of benefits in SBP 130–139 at baseline, fig 4 in paper
- Results similar in trials of people with and without CVD at baseline figure 5
- **CVD+** 0.77 (95% CI: 0.71–0.81)
- **CVD-** 0.74 (95% CI: 0.67–0.83)

- **Total deaths**
- **CVD+** 0.90 (95% CI: 0.83–0.98)
- **CVD-** 0.84 (95% CI: 0.75–0.93)

**Limitations:**
- Lack of individual pt data, which would have allowed a more reliable assessment of treatment effects in different pt groups.
- Interpretation: Lowering of BP into what has been regarded the normotensive range should therefore be routinely considered for the prevention of CVD among those deemed to be of sufficient absolute risk.

Baseline SBP (<130 mm Hg), and major CV events were clearly reduced in high-risk pts with various baseline comorbidities. Both of these major findings—the efficacy of BP-lowering below 130 mm Hg and the similar proportional effects in high risk populations—are consistent with and extend the findings of the SPRINT trial.
### SPRINT
Wright JT Jr, et al., 2015 (114) 26551272

**Aim:** To test the effectiveness of a goal SBP<120 mm Hg vs. a goal SBP<140 mm Hg for the prevention of CVD in pts with SBP≥130 mm Hg at baseline.

**Study type:** RCT

**Size:** 9361 pts followed median of 3.26 y.

**Inclusion criteria:** SBP≥130 mm Hg, with upper limit varying as number of pre-trial BP-lowering meds increased. age ≥50 y Presence of at least 1 of the following:
- Clinical or subclinical CVD
- CKD stage ≥3
- Age≥75
- Framingham General CVD risk≥15% in 10 y

**Exclusion criteria:** DM, history of stroke, ESRD (eGFR <20)

**Intervention:** Intensive BP-lowering treatment to goal SBP <120 mm Hg

**Comparison:**
- Standard BP-lowering treatment to goal SBP<140 mm Hg
- Net treatment difference ~3 drugs (2.8) on average vs. 2 drugs (1.8) on average
- During the trial, mean SBP was 121.5 vs. 134.6.

**1° endpoint:** CVD (MI, ACS, stroke, HF, CVD death) HR: 0.75 (95% CI: 0.64, 0.89)

**Other endpoints:**
- Total deaths HR: 0.73 (95% CI: 0.60–0.90)
- 1° or death HR: 0.78 (95% CI: 0.67–0.90)
- Components of 1° composite mostly consistent in direction other than ACS – no difference.

**CKD outcomes:**
- 1° in CKD pts: reduction in GFR of ≥50% or ESRD HR: 0.89 (95% CI: 0.42, 1.87)
- Incident albuminuria HR: 0.72 (95% 0.48, 1.07)
- In pts without CKD: reduction in GFR ≥30% and to <60
  - HR: 3.49 (95% CI: 2.44–5.10)
  - Incident albuminuria HR: 0.81 (95% CI: 0.63–1.04)

**Adverse events:**
- SAEs: 1.04; p=0.25
- Significant absolute increase seen in intensive group for hypotension (1%), syncope (0.6%), electrolyte abnormality (0.8%), acute kidney injury/acute renal failure (1.6%) over the study period.

**Summary:**
- More intensive SBP lowering to a goal of <120 mm Hg with achieved mean of approximately 121 mm Hg resulted in less CVD and lower total mortality over 3.26 y in comparison with a goal SBP <140 mm Hg and achieved SBP of ~135 mm Hg.
- There were small increases in some expected SAEs. Perhaps unexpected, a sizable increase in reduced eGFR in the non-CKD group and AKI/ARF overall was observed in the intensive group. While of uncertain etiology and significance, there is speculation this could be an acute hemodynamic effect, especially given the findings regarding albuminuria.

**Limitations:** Few pts were untreated at baseline ~9%, so SPRINT provides little if any insight at present regarding BP-lowering medication initiation for untreated people with SBP 130–139.

---

© 2017 American College of Cardiology Foundation and American Heart Association, Inc.
| Lawes MR, et al., 2009 (115) 16222626 | **Aim:**
- To determine the quantitative efficacy of different classes of BP-lowering drugs in preventing CHD and stroke, and who should receive treatment.
- 5 questions encapsulate this uncertainty. 1st, do BBs have a special effect over and above lowering BP in preventing CHD events in people with a history of CHD? 2nd, does the effect of BP-lowering drugs in preventing CHD and stroke differ in people with and without a history of CVD (i.e., is there a different effect in 2° and 1° prevention)? 3rd, does BP reduction alone explain the effect of BP-lowering drugs in preventing CHD and stroke? 4th, should the use of BP-lowering drugs be limited to people with high BP and not given to those at high risk of CVD?

| **Inclusion criteria:** The database search (by MRL) used Medline (1966 to December 2007; any language) to identify randomized trials of BP-lowering drugs in which CHD events or strokes were recorded (irrespective of whether BP reduction was considered the mechanism of action). Search terms were “antihypertensive agents” or “HTN” or “diuretics, thiazide” or “adrenergic beta-antagonists” or “angiotensin-converting enzyme inhibitors” or “receptors, angiotensin/antagonists & inhibitors” or “tetrazoles” or “CCB s” or “vasodilator agents” or the names of all BP-lowering drugs listed in the British National Formulary as keywords or text words. Limits were Medline publication type “clinical trial” or “controlled clinical trial” or “RCT” or “meta-analysis”. We also searched the Cochrane Collaboration and Web of Science databases and the citations in trials and previous meta-analysis and review articles.

| **Exclusion criteria:** We excluded nonrandomized trials and trials in which treated groups but not control groups

| **Intervention:** BP-lowering medications

| **Comparison:** Placebo or less intensive treatment

| **1° endpoint:**
- CHD and stroke co-1°
- Standardized to a 10/5 mm Hg BP reduction

- Overall
  - CHD: 0.78 (95% CI: 0.73–0.83)
  - Stroke: 0.59 (95% CI: 0.52–0.67)
- In absence of vascular disease
  - CHD: 0.79 (95% CI: 0.72–0.86)
  - Stroke: 0.54 (95% CI: 0.45–0.65)
- History of CHD
  - CHD: 0.76 (95% CI: 0.68–0.86)
  - Stroke: 0.65 (95% CI: 0.53–0.80)
- History of stroke
  - CHD: 0.79 (95% CI: 0.62–1.00)
  - Stroke: 0.66 (95% CI: 0.56–0.79)
- No big drug class effects except more benefit for BBs shortly after MI.
- Treatment benefits seen down to pre-treatment SBP of 110–119 mm Hg for CHD events RR: 0.78 (95% CI: 0.63–0.96) and 130–139 mm Hg for stroke RR: 0.75 (95% CI: 0.63–0.89)

| **Summary:** The effect of BP-lowering drugs in reducing the risk of disease is entirely or largely due to BP reduction, with 1 main exception, a special extra effect of BBs in people who have had a recent MI. The proportional reduction in CHD events and stroke for a given reduction in BP, an approximate halving in risk for each 10 mm Hg diastolic reduction, is the same in people with and without a history of vascular disease and in people without high BP as well as in those with high BP. There is benefit in lowering BP in anyone at sufficient CV risk whatever their BP, so avoiding the need to measure BP routinely.

| **Limitation:**
- Most of the pts without HTN were in the trials of people with pre-existing CVD; hence, most of the results of BP lowering in people with SBP<140 are in people with CVD.
- No absolute risks or benefits provided. Not possible to estimate how far down the risk curve these results apply.

| **Interpretation:** This MA provides stronger support for...
who have a lower BP? A corollary is whether BP should be reduced to a limited extent only, a treat to target approach. Although cohort (prospective/observational) studies do not show a lower BP limit below which risk ceases to decline ("the lower the better"), this has not been shown in randomized trials across a wide range of BP. Finally, what is the quantitative effect of taking ≥1 BP-lowering drugs in lowering BP and preventing CHD events and stroke according to dose, pretreatment BP, and age? To date no such quantitative summary of effect, taking account of these determining factors, has been made.

**Study type:** Meta-analysis of RCTs

**Size:** 147 RCTs of BP-lowering meds and CHD events (22,000) and stroke (12,000).

had other interventions as well as BP reduction, such as cholesterol reduction. We excluded trials in pts with chronic renal failure because these pts typically have high BP and high rates of CVD and their response to standard BP-lowering therapy may differ from other people. We also excluded trials in which fewer than 5 CHD events and strokes were recorded or the duration of treatment was less than 6 mo, as these data would contribute little to the overall results and substantially increase the complexity of the analyses. RCTs were otherwise included irrespective of pt age, disease status, BP before treatment, or use of other drugs.

treating at levels <140 for people with CVD than for people without CVD.
| Lewington S, et al., 2002 (16) | **Aim:** To describe the age-specific relevance of BP to cause-specific mortality  
**Study type:** Meta-analysis of cohort studies  
**Size:** 61 prospective studies with 12.7 million person-y of observation, 56,000 vascular deaths in 40–89 y. | **Inclusion criteria:** Collaboration was sought from the investigators of all prospective observational studies in which data on BP, blood cholesterol, date of birth (or age), and sex had been recorded at a baseline screening visit, and in which cause and date of death (or age at death) had been routinely sought for all screens during more than 5,000 person-y of follow-up (see appendix A; http://image.thelancet.com/extra/s01art8300webappendixA.pdf). Relevant studies were identified through computer searches of Medline and Embase, by hand-searches of meeting abstracts, and by extensive discussions with investigators.  
**Exclusion criteria:** To minimize the effects of reverse causality (whereby established disease could change the usual BP), studies were excluded if they had selected pts on the basis of a positive history of stroke or heart disease, and individuals from contributing studies were excluded from the present analyses if they had such a history recorded at baseline. | **Intervention:** N/A  
**Comparator:** N/A  
- The exposures of interest were the level of SBP and DBP and age-group.

  80–89: 0.70 (95% CI: 0.65–0.75)  
- Similar results for DBP also in figure 1.  
- Similar results for men and women separately for stroke, figure 3, and IHD, figure 5.  
**Summary:** Throughout middle and old age, usual BP is strongly and directly related to vascular (and overall) mortality, without any evidence of a threshold down to at least 115/75 mm Hg. | | Thomopoulos C, et al., 2014 (20) | **Aim:** Investigating whether all grades of HTN benefit from BP-lowering treatment and which are the target  
**Inclusion criteria:** Intentional BP-lowering comparing active drug treatment with placebo, or less active treatment (intentional BP-lowering trials), or comparison of an active drug  
**Intervention/Comparator:** Criteria of eligibility were intentional BP-lowering comparing active drug treatment with placebo, or less active treatment  
**1° endpoint:**  
- As some trials were done on low-risk pts, others on higher risk pts, no evaluation of absolute risk-reduction was made. However, a 2° analysis was done including achieving <130/80 mm Hg.  
**Summary:** Meta-analyses favor BP-lowering treatment even in grade 1 HTN at low-to-moderate risk, and lowering SBP/DBP to <140/90 mm Hg. Achieving <130/80 mm Hg. |
| BP levels to maximize outcome reduction. | with placebo over baseline antihypertensive treatment, resulting in a BP difference of at least 2 mm Hg in either SBP or DBP (nonintentional BP-lowering trials); enrolling of hypertensive individuals only or a high proportion (at least 40%) of them. | (intentional BP-lowering trials), or comparison of an active drug with placebo over baseline antihypertensive treatment, resulting in a BP difference of at least 2 mm Hg in either SBP or DBP (nonintentional BP-lowering trials); enrolling of hypertensive individuals only or a high proportion (at least 40%) of them. Other inclusion criteria can be found in the preceding paper. 51 trials were found eligible either for assessing BP-lowering effects in different HTN grades or for assessing the effects of achieving different BP levels. | trials or trial subgroups with mean baseline SBP/DBP values in grade 1 range and a low-to-moderate risk (<5% CV deaths in 10 y in controls): FEVER stratum with baseline SBP below the median (<153 mm Hg) (e7); HTN Detection and Follow-up Program stratum with baseline DBP 90–94 mm Hg and no CVD (e9); OSLO (e17); TOMHS (e28) and USPHS (e29). Risks of stroke, CHD, the composite of stroke and CHD, and all-cause death were significantly reduced by BP-lowering in these low-to-moderate risk pts (control group: average CV mortality 4.5% in 10 y) with a moderate BP elevation (average SBP/DBP 145.5/91 mm Hg) at randomization. Standardized risk ratio associated with 10/5 reduction in BP: stroke 0.33 (95% CI: 0.11–0.98) CHD 0.68 (95% CI: 0.48–0.95) CVD death 0.57 (95% CI: 0.32–1.02) total death 0.53 (95% 0.35–0.80) • Compared outcomes of achieved on study SBP <130 vs. ≥130 Standardized Risk ratio associated with 10/5 reduction in BP: stroke 0.68 (95% CI: 0.57, 0.83) CHD 0.87 (95% CI: 0.76, 1.00) HF 0.92 (95% CI: 0.47, 1.77) CVD 0.81 (95% CI: 0.67, 1.00) CVD death 0.88 (95% CI: 0.77, 1.01) total death 0.88 (95% CI: 0.77, 0.99) • Outcomes of achieved on study SBP 130–139 vs. ≥140 appears safe, but only adds further reduction in stroke. |
| Study type: Meta-analysis of RCTs | Size: 32 RCTs with 104,359 pts | Exclusion criteria: N/A | |
Standardized Risk ratio associated with 10/5 reduction in BP: stroke 0.63 (95% CI: 0.52–0.77) CHD 0.77 (95% CI: 0.70–0.86) HF 0.76 (95% CI: 0.47–1.25) CVD 0.74 (95% CI: 0.62–0.88) CVD death 0.81 (95% CI: 0.67–0.97) total death 0.87 (95% CI: 0.75–1.00)

• Similar pattern of results for on-treatment DBP.

Lonn EM, et al., 2016 (116) 27041480

- **Aim:** To assess efficacy of fixed-dose antihypertensive therapy in adults with intermediate CVD risk.
- **Study type:** Double-blind, placebo-controlled RCT, factorial design
- **Size:** 12,705 pts

**Inclusion criteria:** Men ≥55 y and women ≥60 y at intermediate risk for CVD. No BP restrictions.

**Exclusion criteria:**
- Known CVD
- Indications or contraindications to study meds
- Mod/advanced CKD
- Symptomatic hypotension

**Intervention:** FDC of ARB (candesartan 16 mg/d) and diuretic (hydrochlorothiazide 12.5 mg/d) or placebo

**Follow-up:** Median=5.6 y

**1° endpoint:** 1 co-1° CVD composite outcomes
- CVD mortality, nonfatal MI, nonfatal stroke
- Above plus cardiac arrest, HF, revascularization

**Summary:**
- SBP/DBP reduction of 6.0/3.0 mm Hg
- No difference in treatment effect
- 1st co-1° 0.93 (0.79–1.10)
- 2nd co-1° 0.95 (0.81–1.11)
- Suggestion of a subgroup effect in tertile with the highest baseline BP and increased CVD risk.

Neaton JD et al., 1993 (117) 8336373

- **Aim:** To compare 6 antihypertensive drugs (representing different drug classes)
- **Study type:** Double-blind, placebo-controlled RCT
- **Size:** 902 pts with stage 1 HTN

**Inclusion criteria:**
- Men and women 45–69 y
- Not taking antihypertensive medications, with DBP 90–99 mm Hg
- Taking 1 antihypertensive medication, with DBP <95 mm Hg and between 85–99 mm Hg after withdrawal of BP medications

**Intervention:** Treatment (number): Once daily (AM):
- Placebo (234)
- Chlorothalidone 15 mg/d (136)
- Acebutolol 400 mg/d (132)
- Doxazosin 2 mg/d (134)
- Amlodipine 5 mg/d (131)
- Enalapril 5 mg/d (135)

**Follow-up:** Median=4.4 y

**1° endpoint:** BP, QoL, side effects, chemistries, ECG, clinical events

**Summary:**
- Drugs (plus diet) more effective compared to placebo (plus diet) for control of BP.
- Minimal differences between drug regimens
### Van Dieren S, et al., 2012 (118) 22677192

**Aim:** To assess differences in treatment effects of a fixed combination of perindopril–indapamide on major clinical outcomes in pts with type 2 DM across subgroups of CV risk.

**Study type:** RCT

**Size:** 11,140 pts with DM-2, from the ADVANCE trial

**Inclusion criteria:** DM-2, aged ≥55 y, with a history of major macrovascular or microvascular disease, or at least 1 other risk factor for vascular disease

**Exclusion criteria:** A definite indication for, or contraindication to, any of the study treatments, a definite indication for long-term insulin treatment or were participating in any other clinical trial.

**Intervention:** Perindopril–indapamide or matching placebo

**1° endpoint:** The Framingham equation was used to calculate 5-y CVD risk and to divide participants into 2 risk groups, moderate-to-high risk (<25% and no history of macrovascular disease), very high risk (>25% and/or history of macrovascular disease).

**Endpoints were macrovascular and microvascular events.**

**Summary:** Relative effects of BP-lowering with perindopril–indapamide on CV outcomes were similar across risk groups whilst absolute effects trended to be greater in the high-risk group.

### Montgomery AA, et al., 2003 (119) 12923409

**Aim:** To estimate the effectiveness and cost-effectiveness of BP-lowering treatment over a lifetime.

**Study type:** Markov decision analysis model comparing treatment and nontreatment of HTN.

**Size:** Hypothetical cohorts for 20 different strata of sex, age (30–79 y, in 10-y bands), and CV risk (low and high)

**Inclusion criteria:** We created models for 20 different strata of sex, age (age 30–70 y in 10-y bands), and 2 risk profiles (designated as ‘low’ and ‘high’ risk). These example risk profiles represent the extremes of absolute CV risk, based on data from the Health Survey for England and using a Framingham risk function. We recognize that the risk of most individuals seen in primary care will be somewhere between the examples presented here. The data included were as follows: age- and sex-specific mean SBP of untreated individuals with SBP>0.160 mm Hg were used for both high-risk and low-risk profiles. In addition, low-risk profile was defined as nonsmoker, 10th percentile total cholesterol 90th percentile HDL

**Intervention:** Treatment and nontreatment of HTN.

**1° endpoint:** Life expectancy, and incremental cost: effectiveness ratios for treatment and nontreatment strategies

**Summary:** Incremental cost per quality-adjusted life y among low-risk groups ranged from £1,030 to £3,304. Cost-effectiveness results for low-risk pts were sensitive to the utility of receiving antihypertensive treatment. Treatment of high-risk individuals was highly cost-effective, such that it was the dominant strategy in the oldest age group, and resulted in incremental costs per quality-adjusted life y ranging from £34–£265 in younger age groups.

**• Policy decisions about which pts to treat depend on whether a life-expectancy or cost-
cholesterol, no DM, and no LVH, and high-risk profile was defined as smoker, 90th percentile total cholesterol, 10th percentile HDL cholesterol, DM, and LVH.

**Exclusion criteria:** N/A

<table>
<thead>
<tr>
<th>Aim: Consideration of absolute risk has been recommended for making decisions concerning preventive treatment in HTN. Aim to estimate the benefit of antihypertensive therapy over a lifetime.</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Study type:</strong> Meta-analysis on individual data in HTN and specific cause of death from national statistics. Disease-free survival curves until all pts have died were built using the “life-table” method. The treatment effect estimated from INDANA was applied to this curve to obtain the disease-free</td>
</tr>
<tr>
<td><strong>Inclusion criteria:</strong> To estimate the rate of cv and non-CV deaths in a hypothetical U.S. population of untreated hypertensive pts, we used the following procedure: age-specific death rates in the U.S. general population were obtained from national vital statistics (1994), and in untreated hypertensive population they were obtained from the control groups of the INDANA database. This latter group represents a unique cohort of 14 942 untreated or placebo-treated hypertensive pts, 26–96 y with an average follow-up of 5 y</td>
</tr>
<tr>
<td><strong>Intervention:</strong> The gain in life expectancy without stroke, CHD, and CV events was estimated from the area between the 2 survival curves of treated and control groups. The relative gain in life expectancy was defined as the ratio of gain in life expectancy to life expectancy.</td>
</tr>

</tr>
<tr>
<td><strong>Summary:</strong> Absolute gains in life expectancy are likely to be greater for younger, lower risk people with HTN than for older, higher risk people with HTN. However, the NNT to prevent an event will likely be greater especially in the short term in younger, lower risk people. This modeling analysis provides support for treating younger, lower risk individuals with HTN, but relies on the assumption that the relative benefits of treatments observed in short-term trials of higher risk individuals applies over a longer term to lower risk individuals.</td>

<td>VA NEPHRON-D Fried LF, et al., 2013 (124) 24206457</td>
<td><strong>Aim:</strong> Assess the efficacy of combination of an ACEI and an ARB vs. ARB monotherapy in reducing the progression of proteinuric diabetic nephropathy <strong>Study type:</strong> Multicenter, double-blind, RCT at 32 VA Medical Centers <strong>Size:</strong> 1448 pts</td>
<td><strong>Inclusion criteria:</strong> Pts with type 2 DM, a urinary albumin-to-creatinine ratio of ≥300, and an eGFR 30.0–89.9 mL/min/1.73 m² <strong>Exclusion criteria:</strong> • Subjects with known nondiabetic kidney disease • Serum K+ &gt;5.5 mmol/L • Current treatment with sodium polystyrene sulfonate • Inability to stop prescribed medication that increases the risk of hyperkalemia</td>
<td><strong>Intervention:</strong> Losartan 100 mg daily plus lisinopril 10–40 mg daily (n=724) <strong>Comparator:</strong> Losartan 100 mg daily plus placebo (n=724)</td>
<td><strong>1° endpoint:</strong> After a median follow-up of 2.2 y, the study was stopped early due to safety concerns. There was no difference in the 1° outcome of first occurrence of change in eGFR (decrease of ≥30 mL/min/1.73 m² if initial GFR was ≥60 mL/min/1.73 m² or a decline of ≥50% if initial eGFR was &lt;60 mL/min/1.73 m²), ESRD, or death (HR with combination therapy: 0.88; 95% CI: 0.70–1.12; p=0.30).</td>
<td><strong>Safety endpoint:</strong> Combination therapy increased the risk of hyperkalemia (HR: 2.8; 95% CI: 1.8–4.2; p&lt;0.001) and acute kidney injury (HR: 1.7; 95% CI: 1.3–2.2; p&lt;0.001). <strong>Summary:</strong> Combination therapy of losartan plus lisinopril did not improve renal outcomes compared to losartan alone, and was associated with greater risk of acute kidney injury and hyperkalemia.</td>
</tr>
<tr>
<td>ALTITUDE Parving HH, et al., 2012 (125) 23121378</td>
<td><strong>Aim:</strong> Determine if addition of aliskiren as an adjunct to an ACEI or ARB reduces the risk of CV and renal events in pts with type 2 DM</td>
<td><strong>Inclusion criteria:</strong> • ≥35 y with type 2 DM • On ACEI or ARB • At least 1 of the following: persistent macroalbuminuria (urine microalbumin to creatinine ratio ≥200 mg/g) and eGFR ≥30 mL/min/1.73 m², persistent microalbuminuria (≥20 mg/g and &lt;200 mg/g) and a mean eGFR ≥30 and &lt;60</td>
<td><strong>Intervention:</strong> Aliskiren 300 mg daily added to conventional treatment with an ACEI or ARB (n=4,274) <strong>Comparator:</strong> Placebo (n=4,287)</td>
<td><strong>1° endpoint:</strong> After a median follow-up of 32.9 mo the study was stopped early. There was no difference in the 1° composite outcome death from CV causes or first occurrence of cardiac arrest with resuscitation; nonfatal MI; nonfatal stroke; MI, CHF, and stroke (p&gt;0.05 for all).</td>
<td><strong>2° endpoint:</strong> There was no difference in the 2° endpoint of first occurrence of change in eGFR or ESRD (HR: 0.78; 95% CI: 0.58–1.05; p=0.10). There were no differences between combination therapy or losartan monotherapy for the endpoints of ESRD, death, composite of MI, HF, or stroke, MI, CHF, and stroke (p&gt;0.05 for all). <strong>Summary:</strong> Combination therapy of losartan plus lisinopril did not improve renal outcomes compared to losartan alone, and was associated with greater risk of acute kidney injury and hyperkalemia.</td>
</tr>
</tbody>
</table>
### Study type:
Doubled-blind, multicenter RCT

### Size:
8561

#### Inclusion criteria:
- ≥55 y
- Coronary, peripheral, or cerebrovascular disease or DM with end-organ damage

#### Exclusion criteria:
- Inability to discontinue ACEI or ARB
- Known hypersensitivity or intolerance to ACEI or ARB
- Selected CVDs (congestive HF, hemodynamically significant valvular or outflow tract obstruction, constrictive pericarditis, complex congenital heart disease, syncopal episodes of unknown etiology <3 mo, planned cardiac surgery

#### Intervention:
- Ramipril 10 mg daily (n=8,576)

#### Comparator:
- Telmisartan 80 mg daily (n=8,542)
- Combination of telmisartan and ramipril (n=8,502)

#### 1° endpoint:
After a median follow-up of 56 mo, there was no difference between ramipril vs. telmisartan or combination therapy vs. ramipril in the 1° composite outcome of death from CV causes, MI, stroke, or hospitalization for HF (RR: 1.01; 95% CI: 0.94–1.09 and RR: 0.99; 95% CI: 0.92–1.07, respectively)

#### Safety endpoint:
- Combination therapy was associated with greater risk of hyperkalemia than

#### 2° endpoint:
- There was no differences in composite of death from CV causes, MI, or stroke in the ramipril vs. telmisartan or combination therapy vs. ramipril in the 2° outcomes including MI, stroke, hospitalization for HF, death from CV causes, death from non-CV causes, or death from any cause (p>0.05 for all).

---

### Study type:
Multi-center, double-blind, RCT

### Size:
8561

#### Inclusion criteria:
- mL/min/1.73 m², or history of CVD (e.g., MI, stroke, HF, or CAD) and a mean eGFR ≥30 and <60 mL/min/1.73 m²

#### Exclusion criteria:
- Serum K+ >5.0 mmol/L
- Type 1 DM
- Unstable serum Cr
- CV history (NYHA Class III or IV, SBP ≥170 mm Hg or DBP ≥110 mm Hg or SBP ≥135 and <170 mm Hg or DBP ≥82 and <100 mm Hg with at least 3 agents, 2nd or third degree heart block, renal artery stenosis
- Surgical or medical conditions (malignancy in last 5 y, <2 y life expectancy, renal transplant or immunosuppressive therapy, drug/alcohol abuse, hypersensitivity/allergy/contraindication to study drugs, pregnancy)
- Concomitant treatment with ≥2 agents blocking RAAS or K⁺-sparing diuretics.

#### Intervention:
unplanned hospitalization for HF; ESRD; death attributable to kidney failure or need for renal-replacement therapy with no dialysis or transplantation available or initiated; or doubling of the baseline serum Cr between aliskiren or placebo (HR: 1.08; 95% CI: 0.98–1.20; p=0.12).

#### Safety endpoint:
The combination of aliskiren added to an ACEI or an ARB was associated with greater risk of hyperkalemia and hypotension (11.2% vs. 7.2% and 12.8% vs. 8.3%; p<0.001 for both, respectively).

---

### Aim:
Evaluate whether use of an ARB was noninferior to ACEI, and whether the combination was superior to ACE alone in the prevention of vascular events in pts with CVD or DM but not HF.

### Study type:
Multi-center, double-blind, RCT

### Inclusion criteria:
- ≥55 y
- History of CVD (e.g., MI, stroke, HF, or CAD) and a mean eGFR ≥30 and <60 mL/min/1.73 m²

### Exclusion criteria:
- Serum K+ >5.0 mmol/L
- Type 1 DM
- Unstable serum Cr
- CV history (NYHA Class III or IV, SBP ≥170 mm Hg or DBP ≥110 mm Hg or SBP ≥135 and <170 mm Hg or DBP ≥82 and <100 mm Hg with at least 3 agents, 2nd or third degree heart block, renal artery stenosis
- Surgical or medical conditions (malignancy in last 5 y, <2 y life expectancy, renal transplant or immunosuppressive therapy, drug/alcohol abuse, hypersensitivity/allergy/contraindication to study drugs, pregnancy)
- Concomitant treatment with ≥2 agents blocking RAAS or K⁺-sparing diuretics.

---

### Summary:
Aliskiren added to background treatment of an ACEI or ARB did not decrease CV or renal outcomes, and was associated with increased risk of cardiac arrest with resuscitation, hyperkalemia, and hypotension.
or PTCA <3 mo, uncontrolled HTN on treatment [e.g., BP >160/100 mm Hg], heart transplant recipient, stroke due to subarachnoid hemorrhage
• Other conditions (significant renal artery disease, hepatic dysfunction, uncorrected volume or sodium depletion, 1° hyperaldosteronism, hereditary fructose intolerance, other major noncardiac illness or expected to reduce life expectancy or significant disability interfere with study participation, simultaneously taking another experimental drug, unable to provide written informed consent).

<td>N/A</td>
<td>N/A</td>
<td>In general, there were linear associations between achieved SPB and risk of CVD and all-cause mortality, with the lowest risk at a SBP of 120–124 mm Hg. This was by far the largest and best powered meta-analysis to assess the relationship between SBP reduction and major outcomes during treatment of hypertension. The findings provided strong evidence for the “lower is better” approach to treatment in patients with a high SBP who are at high risk for CVD.</td>

| Xie X, et al., 2015 (21) 26559744    | **Aim:** To assess the efficacy and safety of intensive BP-lowering strategies.  
**Study type:** Meta-analysis of RCTs  
**Size:** 19 RCTs with 44,989 pts | **Inclusion criteria:** RCTs with at least 6 mo follow-up that randomly assigned pts to more intensive vs. less intensive BP-lowering treatment, with different BP targets or different BP changes from baseline. Reference lists from identified trials and review articles were manually scanned to identify any other relevant studies.  
**Exclusion criteria:** N/A | **Intervention:** BP-lowering meds  
**Comparator:**  
• Less intensive treatment  
• BP difference 6.8/3.5  
• The mean follow-up BP levels in the less intensive BP-lowering regimen group were 140/81 mm Hg, compared with 133/76 mm Hg in the more intensive treatment group. | **1° endpoint:**  
• CVD, other major CV events, defined as a MI, stroke, HF, or CV death, separately and combined; nonvascular and all-cause mortality; ESKD, and adverse events. Progression of albuminuria (defined as new onset of micro-albuminuria/macro-albuminuria or a change from micro-albuminuria to macro-albuminuria) and retinopathy (retinopathy progression of 2 or more steps) were also recorded for trials that were done in pts with DM  
• CVD RR: 0.86 (95% CI: 0.78–0.96) | **Summary:** Intensive BP-lowering, including to <130 mm Hg, provided greater vascular protection than standard regimens. In high-risk pts, there are additional benefits from more intensive BP-lowering, including for those with SBP <140 mm Hg at baseline. The net absolute benefits of intensive BP-lowering in high-risk individuals are large.  
**Limitations:**  
• Lack of individual pt data, which would have allowed a more reliable assessment of...
### Other endpoints:
- MI RR: 0.87 (95% CI: 0.76–1.00)  p=0.042
- Stroke RR: 0.78 (95% CI: 0.68–0.90)
- HF RR: 0.85 (95% CI: 0.66–1.11)
- CVD death RR: 0.91 (95% CI: 0.74–1.11)
- Total deaths RR: 0.91 (95% CI: 0.81–1.03)

### Other results:
- Benefit for CVD not different by baseline SBP
  - 120–139: 0.89 (95% CI: 0.76–1.05)
  - 140–160: 0.83 (95% CI: 0.68–1.00)
  - >160: 0.89 (95% CI: 0.73–1.09)  p-heterogeneity: 0.60
- Benefit for CVD not different for more intensive and less intensive targets in intensive group
  - <140 or <150 mm Hg: 0.76 (95% CI: 0.60–0.97)
  - <120–<130 mm Hg: 0.91 (95% CI: 0.84–1.00; p-hetero: 0.06)
- Absolute benefits were proportional to absolute risk.
- For trials in which all pts had vascular disease, renal disease, or DM at baseline, the average control group rate of major vascular events was 2.9% per y compared with 0.9% per y in other trials, and the numbers needed to treat were 94 (95% CI: 86–103)  p=0.002

### Interpretation:
- Supports treating pt with and without CVD at threshold of 130 to <130. Supports treating at threshold of about 130 even down to a CVD event rate of 0.9% per y.

| Ambrosius WT, et al., 2014 (122) 24902920 | **Aim:** To describe the study design of the SPRINT trial  
**Study type:** description of study design and protocol for the SPRINT RCT | **Inclusion criteria:** Adults ≥50 y, average SBP ≥130 mm Hg and evidence of CVD, CKD, or 10-y Framingham risk score ≥15%, or age ≥75 y | **Intervention:** 9361 participants randomized to 2 treatment groups: (1) Standard treatment group, SBP target <140 mm Hg, and (2) Intensive treatment group: SBP target <120 mm Hg. | **1° endpoint:** MI, ACS, stroke, HF, or CVD death. | **Relevant 2° endpoint:** All-cause mortality, decline in kidney function or development of ESRD, incident dementia, decline in cognitive function, and small-vessel cerebral ischemic disease  
**Summary:** This paper describes the protocol followed in the SPRINT trial that was successful in helping participants to attain and maintain BP targets in the study groups. Once treated, participants had follow-up visits to assessment BP control monthly until BP was at target. Medications were titrated and added as per protocol, when target BP was not attained. |
| Cushman WC, et al., 2007 (123) 17599425 | **Aim:** To describe the study design of the BP trial of the ACCORD trial.  
**Study type:** description of study design and protocol | **Inclusion criteria:** Adults with a diagnosis of type 2 DM for at least 3 mo and at high risk for CVD events, who meet the following BP criteria: (1) SBP 130–160 mm Hg and taking 0–3 antihypertensive medications; (2) SBP 161–170 and on 0–2 antihypertensive | **Intervention:** • Unmasked, open-label, factorial design, randomized trial with a sample size of 4,733 pts  
• Patients were randomized to intensive SBP control (<120 mm Hg) or standard control (<140 mm Hg) | **1° endpoint:** Major CVD event (nonfatal MI or stroke, or CV death) | **Relevant 2° endpoint:** Expanded macrovascular outcome (1° outcome plus coronary revascularization or HF hospitalization), total mortality, each of the separate components of the 1° outcome, HF death or hospitalization, and |
Xu W, et al., 2015 (128) 25655523

**Aim:** Retrospective assessment of the impact of follow-up intervals and treatment intensification thresholds on CVD events

**Study type:** Retrospective cohort

**Size:** 88,756 adult pts with HTN from The Health Improvement Network database

**Inclusion criteria:** Primary care practices in the U.K., 1986–2010.

**N/A**

- Median follow-up of 37.4 mo after the treatment strategy assessment period
- 9,985 (11.3%) pts had an acute CV event or died.
- No difference in risk of the outcome with systolic intensification thresholds 130–150 mm Hg, but HR: 1.21 for thresholds >150 mm Hg
- Outcome risk increased progressively from the lowest (0–1.4 mo) to the highest 5th of time to medication intensification (HR: 1.12; 95% CI: 1.05–1.20; p=0.009) for intensification between 1.4 and 4.7 mo after detection of elevated BP). The highest fifth of time to follow-up (>2.7 mo) was also associated with increased outcome risk HR:

- Increased risk of acute CVD event or death with:
  - Systolic intensification thresholds >150 mm Hg
  - Delays of >1.4 mo before medication intensification after SBP elevation
  - Delays of >2.7 mo before BP follow-up after antihypertensive medication intensification
  - Timely medical management and follow-up impacts outcomes in the treatment of pts with HTN.
  - Retrospective study, but still sheds important light on the impact of follow-up actions

</table>
| Bosworth, et al., 2009 (131) | **Aim:** Assess impact of telephone follow-up intervention and/or home BP monitoring on BP control in pts with treated HTN  
**Study type:** RCT  
**Size:** 636 pts were randomized; 475 pts completed the trial, including 24-mo follow-up period. | **Inclusion criteria:** Pts with HTN, from 2 university-affiliated primary care clinics.  
- 636 pts randomized to usual care or 1 of 3 intervention groups: (1) Nurse-administered telephone intervention targeting HTN-related behaviors, (2) home BP monitoring 3 times weekly, and (3) both interventions | • 636 pts randomized to usual care or 1 of 3 intervention groups: (1) Nurse-administered telephone intervention targeting HTN-related behaviors, (2) home BP monitoring 3 times weekly, and (3) both interventions  
• 475 pts (75%) completed the 24-mo BP follow-up.  
• At 24 mo, improvements in the proportion of pts with BP control relative to the usual care group were 4.3% (95% CI: -4.5%, 12.9%) in the behavioral intervention group, 7.6% (95% CI: -1.9%, 17.0%) in the home BP monitoring group, and 11.0% (95% CI: 1.9%, 19.8%) in the combined intervention group.  
• Relative to usual care, the 24-mo difference in SBP was 0.6 mm Hg (95% CI: -2.2, 3.4 mm Hg) for the behavioral intervention group, -0.6 mm Hg (95% CI: -3.6, 2.3 mm Hg) for the BP monitoring group, and -3.9 mm Hg (95% CI: -6.9, -0.9 mm Hg) for the combined intervention group; patterns were similar for DBP | **Home BP monitoring and tailored behavioral telephone intervention improved BP control, SBP, and DBP at 24 mo relative to usual care. Combined therapy was significantly better than either therapy alone.** |

| Bosworth, et al., 2011 (132) | **Aim:** Assess impact of telephone follow-up interventions on BP control in pts with treated HTN  
**Study type:** RCT  
**Size:** Of 1551 eligible pts, 593 randomized | **Inclusion criteria:** Primary care clinics at a VA Medical Center  
- 593 pts randomized to either usual care or to 1 of 3 telephone follow-up groups: (1) nurse-administered behavioral management, (2) nurse- and physician-administered medication management, or (3) a combination of both  
- 1° endpoint: BP control measured every 6 mo for 18 mo  
- Behavioral management and medication management alone showed significant improvements at 12 mo-12.8% (95% CI: 1.6%, 24.1%) and 12.5% (95% CI: 1.3%, 23.6%), respectively-but not at 18 mo.  
- In subgroup analyses, among those with poor baseline BP control, SBP decreased in the combined intervention group by 14.8 mm Hg (95% CI: -21.8, -7.8 mm Hg) at 12 mo and 8.0 mm Hg (95% CI: -15.5, -0.5 mm Hg) at 18 mo, relative to usual care. | **Telephone-based case management for high BP control effectively lowers BP for up to 1 y, but then BP control slackens.**  
**Interventions had the most impact on pts with worst BP control at study entry.**  
**Study carried out in the Veteran’s Administration outpatient practice; unclear if results would apply to other practice settings.** |

<td>Cluster RCT</td>
<td>778 pts from 16 clinics in integrated group practice in Washington state.</td>
<td>Intervention group with all components achieved better BP control vs. usual care • 56% (95% CI: 49%–62%) or combination intervention group achieved BP control vs. usual care (p&lt;0.001) and intervention with only home BP monitor and Internet tool (p&lt;0.001) • Combination of home BP monitoring, Internet-based BP management tools, and pharmacist care management helped control HTN better than usual care and better than BP monitoring and Internet-based tool alone.</td>
</tr>
<tr>
<td>Heisler M, et al., 2012 (134) 22570370</td>
<td>Assess impact of follow-up pharmacist care management system on BP control in pts treated for HTN</td>
<td>14-mo intervention period • BP 6 mo prior to and 6 mo after intervention period were compared in intervention and control groups</td>
<td>Cluster RCT</td>
<td>1797 intervention and 2303 control pts from 16 primary care clinics at 5 medical centers (3 VA and 2 Kaiser Permanente)</td>
<td>Mean SBP was 2.4 mm Hg lower (95% CI: -3.4--1.5), p&lt;0.001 in the intervention group immediately after the intervention period, compared to the control group. BP decrease was the same in the intervention and control groups (9 mm Hg). • Pharmacist care management system in a “real world” setting was more effective than usual care in lowering BP in the short-term, but in the longer-term follow-up did not differ significantly from usual care. • This study is one of very few studies to show no significant longer term impact of a care management system on BP control in pts with HTN.</td>
</tr>
<tr>
<td>Margolis KL, et al., 2013 (25) 23821088</td>
<td>Assess impact of follow-up and monitoring system including home BP tele-monitoring and pharmacist case management on BP control in pts treated for HTN</td>
<td>222 pts randomized to 8 usual care clinics and 228 randomized to 8 intervention clinics • Intervention included 12 mo of home BP tele-monitoring and pharmacist case management, with 6 mo of follow-up afterward</td>
<td>Cluster RCT</td>
<td>450 pts from 16 clinics in integrated health system in Minneapolis, MN</td>
<td>Intervention group achieved better BP control compared to usual care during 12 mo of intervention and persisting during 6 mo of follow-up • SBP was &lt;140/90 in 57.2% (95% CI: 44.8%, 68.7%) of intervention pts at 6 and 12 mo vs. 30% (95% CI: 23.2%, 37.8%) in usual care (p=0.001) • Combination of home BP tele-monitoring and pharmacist case management helped control HTN better than usual care at 6, 12, and 18 mo</td>

### HOPE
Yusuf S, et al., 2000 (136)

**Aim:** To investigate effect of ACE-I (Ramipril 10 mg) on CV events in high risk pts. over 5y with a mean entry BP of 139/79 mm Hg in both groups  
**Study type:** RCT, 2×2 factorial design  
**Size:** 9,297

**Inclusion criteria:** Pts ≥55 y with history of CAD, stroke, PVD or DM with either HTN, elevated total cholesterol, low LDL cholesterol, smoking, or micro albuminuria.  
**Exclusion criteria:** HF, <0.40 EF, on ACE-I or Vitamin E, uncontrolled HTN/overt nephropathy, Had MI or stroke <4 wk

**Intervention:** Ramipril (10 mg) (4,645)  
**Comparator:** Placebo (4,652)

**1° endpoint:** Composite of MI, stroke, or mortality from CV causes.  
**Results:** Endpoint reduction Ramipril group vs. Placebo (14% vs. 17.8%; RR: 0.78; CI: 0.70–0.86; p<0.001)  
- Death from cardiac causes reduced (6.1% vs. 8.1%; p<0.001)  
- Death from MI reduced (9.9% vs. 12.3%; p<0.001)  
- Death from any cause (10.4% vs. 12.2%; p=0.005)

### SAVE
Pfeffer M., et al., 1992 (137)

**Aim:** To assess if captopril decrease morbidity and mortality in pts with LV dysfunction after MI.  
**Study type:** RCT  
**Size:** 2,231

**Inclusion criteria:** Pts (21–80 y) surviving 3 d after MI, EF≤40%.  
**Exclusion criteria:** Pts not randomized within 16 d after MI, contra. to ACE-I use, Serum Cr. >2.5 mg/dL, severe comorbidities, unstable infarction, need for revascularization

**Intervention:** Captopril (titrated doses) (115)  
**Comparator:** Placebo (1116)

**1° endpoint and results:** All-cause mortality: 20% vs. 25%, RR: 19%; 95% CI: 3%–32%; p=0.019  
- Captopril vs. Placebo group B P at 1 y (125±18 / 77±10 mm Hg for placebo vs. 119±18/74±10 mm Hg for captopril; p<0.001)  
- Dizziness, alteration in taste, cough and diarrhea were reported significantly more in the captopril group  
- Ventricular size on Echo studies was independent predictor of adverse CV outcomes

### EUROPA
Fox KM, et al., 2003 (138)

**Aim:** To investigate efficacy of perindopril in CV events in pts with stable CAD.  
**Study type:** RCT  
**Size:**

**Inclusion criteria:** Pts ≥18 y (women) with CAD >mo before screening, revascularization >6 mo before screening, ≥70% narrowing of major

**Intervention:** Perindopril (6,110)  
**Comparator:** Placebo (6,108)

**1° endpoint:** Composite of CV death, nonfatal MI, cardiac arrest with successful CPR  
**Results:** RR 20%; 95% CI: 9%–29; p=0.0003  
- Perindopril resulted reduction in all these outcomes: composite of total mortality, nonfatal MI, hospital admission for UA, and cardiac arrest with successful CPR; CV mortality and nonfatal MI, the individual components these outcomes and revascularization, stroke, and admission for HF
| **Size:** 12,218 pts | coronary artery. Men with history of chest pain, positive ECG, echo or nuclear test |
| **Exclusion criteria:** HF, planned revascularization, <110 mm Hg SBP, uncontrolled HTN, >100 mm Hg DBP, <1 mo use of ACEI or ARB, Cr>150 µmol/L, serum K>5.5 mmol/L |

**MERIT-HF**  
Goldstein S, et al., 1999 (139)  
10526701  

**Aim:** To investigate if metoprolol (CR/XL) once daily with std. treatment lowers mortality in pts with HFrEF  
**Study type:** RCT  
**Size:** 3,991 pts  

| **Inclusion criteria:** Pts 40–80 y with NYHA class II-IV HF for 3 mo before randomization and on standard treatment 2 wk before entry, Stable clinical condition during 2 wk run-in phase, EF ≤0.40.  
**Exclusion criteria:** Acute MI, UA <28 d of entry, contra to beta blockade <6 mo, HF due to systemic disease/alcohol abuse, heart transplant candidate, ICD, planned revascularization in past 4 mo, decompensated heart, SBP <100 mm Hg, CCB treatment, amiodarone use within 6 mo |

| **Intervention:** Metoprolol CR/XL (1,990)  
**Comparator:** Placebo (2,001) |

| **1° endpoint:** All-cause mortality in the intent to treat |

| **Results:** 145 vs. 217 deaths [11.0 %], RR: 0.66 (95% CI: 0.53–0.81; p=0.00009) or adjusted for interim analyses p=0.0062. |

- Fewer sudden deaths in the metoprolol group (p=0.0002)  
- Lesser deaths from HFrEF in the metoprolol group (p=0.002)  
- Metoprolol improved survival and was well tolerated

**Exclusion criteria:**
SBP<90 mm Hg,
uncontrolled HTN,
bradycardia, insulin-dependent DM, BBS not for HF, Beta-2 agonists and steroids

**MERIT-HF HTN**
Herlitz J, et al., 2002 (142)

| Aim: To assess metoprolol CR/XL influence on mortality and hospitalizations in HF and HTN pts. | **Inclusion criteria:**
Same as above MERIT-HF, 1999 study (HTN subgroup) | **Intervention:**
Metoprolol CR/XL (871) | **1° endpoint:**
Total mortality | **Results:**
RR: 0.61; 95% CI: 0.44–0.84; p=0.0022 |
• Total mortality reduction was driven by reduction in the SCD and death from worsening HF |
• 12.5% pts had earlier discontinuation due to any cause. Lesser no. of pts in the metoprolol group (n=21) discontinued due to worsening HF |
The mean reduction in BP (adjusted) was 1.7 mm Hg in the metoprolol group vs. 4.8 mm Hg in placebo group (p=0.0001) |

| **Study type:** RCT | **Size:** 1,747 pts |

---

**CIBIS-II**
1999 (143)

| Aim: To determine efficacy of bisoprolol in reducing mortality in chronic HF. | **Inclusion criteria:**
18–80 y, LVEF≤35%, dyspnea, orthopnea, fatigue, NYHA class III-IV | **Intervention:**
Bisoprolol (1,327) | **1° endpoint:**
All-cause mortality | **Results:**
11.8% vs. 17.3% deaths with a RR: 0.66; 95% CI: 0.54–0.81; p<0.0001 | • The trial stopped early due to benefit. Bisoprolol group had significantly fewer SCDs. |
• Mean age was 61 y so more data on elderly pts is needed |

| **Study type:** RCT | **Size:** 2,647 pts |

---

**Elkayam U, et al., 1990 (144)**

| Aim: To assess comparative efficacy and safety of nifedipine and ISDN alone and the combination for treating for chronic CHF. | **Inclusion criteria:**
18–75 y HF pts, NYHA class II and III, LVEF<40%, clinically stable, maintenance dose of Digitalis and diuretics. | **Intervention:**
Nifedipine (21), ISDN (20), Nifedipine+ISDN (23) | **Endpoints and Results:**
HF-worsening: 9 in Nifedipine group vs. 3 in ISDN group (p<0.09); and 21 in nifedipine-ISDN group (p<0.001 vs. nifedipine, p<0.0001 vs. ISDN) | • In clinical deterioration nifedipine pts (8) vs. rest of the pts (No difference in LVEF or VO2 max) |
• Although all the 3 drug regimens improved exercise capacity, nifedipine treatment alone or in combination resulted in clinical deterioration and worsening of CHF |

<td>In a follow-up analysis, to compare diuretic vs. alpha-blocker as first step treatment of hypertension.</td>
<td>Men and women ≥ 55 y with BP ≥140/90 mm Hg or on medications for hypertension with at least one additional risk factor for coronary heart disease.</td>
<td>Combined fatal coronary heart disease or non-fatal MI, analyzed by intention to treat.</td>
</tr>
</tbody>
</table>

• There was no difference in primary outcome between the arms (RR: 1.02; 95% CI: 0.94–1.13). However, the doxazosin arm compared with the chlorthalidone arm had a higher risk for stroke (RR: 1.26; 95% CI: 1.10–1.46) and combined cardiovascular disease (RR: 1.20; 95% CI: 1.13–1.27). The findings confirmed the superiority of diuretic-based over alpha blocker based antihypertensive treatment in the prevention of cardiovascular disease.

<tbody>
<tr>
<td>To provide additional analyses of the primary endpoint in the VALUE trial, including sex, age, race, geographic region, smoking status, type 2 diabetes, total cholesterol, left ventricular hypertrophy, proteinuria, serum creatinine, history of coronary heart disease, stroke or transient ischemic attack and history of peripheral artery disease.</td>
<td>The 15,245 patients participating in VALUE were divided into subgroups according to baseline characteristics.</td>
<td>Subgroup interaction analyses were conducted by the Cox proportion hazard model. Within each subgroup, treatment effects were assessed by hazard ratios and 95% CIs.</td>
</tr>
</tbody>
</table>

• For cardiac morbidity and mortality, the only significant subgroup by treatment interaction was of sex (p=0.016) with HR indicating a relative excess of cardiac events in women but not in men, but SBP differences in favor of amlodipine were greater in women. In the VALUE cohort, in no subgroup of patients were there differences in the incidence of the composite cardiac endpoint with valsartan and amlodipine treatment despite greater BP reduction in the amlodipine group.
Aim: To compare the long-term relative safety and outcomes of ACE inhibitor- and CCB-based regimens in older hypertensive individuals in ALLHAT.

Inclusion criteria: men and women age ≥55 y with untreated (BP 140–180/90–110 mm Hg) or treated hypertension (BP ≤160/100 mm Hg on ≤2 antihypertensive drugs) with ≥ 1 additional risk factor for coronary heart disease.

Intervention: Patients were randomized to amlodipine (9,048) or Lisinopril (9,054).

Primary outcome: Combined fatal coronary heart disease or non-fatal MI, analyzed by intention to treat.

Follow-up: 4.9 y

• Risk of coronary heart disease was similar between amlodipine and Lisinopril
• For stroke, combined cardiovascular disease, gastrointestinal bleeding and angioedema, risks are higher with Lisinopril compared to amlodipine.
• For heart failure, risks are higher with amlodipine compared to Lisinopril.

</table>
| Bundy JD, et al., 2017 28564682       | Study type: Network meta-analysis | Size: 144,220 patients in 42 RCTs. | **Inclusion criteria:**
- Random allocation into an antihypertensive medication, control or treatment target
- Allocation to antihypertensive Antihypertensive treatment was independent of other treatment regimens
- ≥100 patients in each treatment group
- Trial duration ≥ 6 mo
- One or more events for each treatment group reported
- Minimum 5 mm Hg difference in SBP level between the 2 treatment groups
- Outcomes included major CVD, stroke, CHD, CVD mortality or all-cause mortality | **Primary endpoint and results**
- There were linear associations between mean achieved SBP and risk of cardiovascular disease and mortality, with the lowest risk at 120 to 124 mm Hg. Randomized groups with a mean achieved SBP of 120 to 124 mm Hg had a hazard ratio (HR) for major cardiovascular disease of 0.71 (95% CI: 0.60–0.83) compared with randomized groups with a mean achieved SBP of 130 to 134 mm Hg, an HR of 0.58 (95% CI: 0.48–0.72) compared with those with a mean achieved SBP of 140 to 144 mm Hg, an HR of 0.46 (95% CI: 0.34–0.63) compared with those with a mean achieved SBP of 150 to 154 mm Hg, and an HR of 0.36 (95% CI: 0.26–0.51) compared with those with a mean achieved SBP of 160 mm Hg or more. | **Summary/Conclusion Comment(s)**
- This study suggests that reducing SBP to levels below currently recommended targets significantly reduces the risk of cardiovascular disease and all-cause mortality and strongly support more intensive control of SBP among adults with hypertension.

<td>PROVE IT-TIMI 22 Bangalore S, et al., 2010 (151) 21060068</td>
<td>Study type: Nonrandomized trial of optimal BP after ACS  Size: 4,162 pts</td>
<td><strong>Inclusion criteria:</strong> Pts with acute MI or high-risk UA within 10 d randomized to pravastatin or atorvastatin and to gatifloxacin or placebo treated with standard medical and interventional treatment for ACS  <strong>Exclusion criteria:</strong> N/A</td>
<td><strong>1° endpoint:</strong> Composite of all-cause death, MI, UA requiring rehospitalization, revascularization after 30 d, and stroke with a mean follow-up of 24 mo  <strong>Results:</strong> The relationship between SBP and DBP followed a J- or U-shaped curve association with the 1° outcome with increased events rates at both low and high BP values. A nonlinear Cox proportional hazards model showed a nadir of 136/85 mm Hg (range 130–140/80–90 mm Hg) at which the incidence of 1° outcome was lowest. There was a relatively flat curve for SBP of 110–130 mm Hg and for DBP of 70–90 mm Hg, suggesting a BP &lt;110/70 mm Hg may be dangerous.</td>
<td>• After an ACS, a J- or U-shaped association existed between BP and the incidence of new CV events. The lowest incidence of CV events occurred with a BP of 130–140/80–90 mm Hg and a relatively flat curve for SBP of 110–130 mm Hg and of DBP of 70–90 mm Hg, suggesting a BP &lt;110/70 mm Hg may be dangerous.</td>
</tr>
<tr>
<td>Law MR, et al., 2009 (18) 19454737</td>
<td>Study type: Meta-analysis of use of BP-lowering drugs in prevention of CVD from 147 randomized trials  Size: Of 147 randomized trials of 464,000 pts, 37 trials of BBs in CAD included 38,892 pts, and 37 trials of other antihypertensive drugs in CAD included 85,395 pts</td>
<td><strong>Inclusion criteria:</strong> The database search used Medline (1966 to Dec. 2007) to identify randomized trials of BP-lowering drugs in which CAD events or strokes were recorded. The search also included the Cochrane Collaboration and Web of Science databases and the citations in trials and previous meta-analyses and review articles.  <strong>Exclusion criteria:</strong> Trials were excluded if there were &lt;5 CAD events and strokes or if treatment duration was &lt;6 mo.</td>
<td><strong>1° endpoint:</strong> CAD events; stroke  <strong>Results:</strong> In 37 trials of pts with a history of CAD, BBs reduced CAD events 29% (95% CI: 22%, 34%). In 27 trials in which BBs were used after acute MI, BBs reduced CAD events 31% (95% CI: 24%–38%), and in 11 trials in which BBs were used after long-term CAD, BBs insignificantly reduced CAD events 13%. In 7 trials, BBs reduced stroke 17% (95% CI: 1%–30%). CAD events were reduced 14% (95% CI: 2%–25%) in 11 trials of thiazide diuretics, 17% (95% CI: 11%–22%) in 21 trials of ACEIs, insignificantly 14% in 4 trials of angiotensin receptor blockers, and 15% (95% CI: 8%–22%) in 22 trials of CCBs. Stroke was reduced 38% (95% CI: 28%–47%) in 10 trials of thiazide diuretics, 22% (95% CI: 8%–34%) in 13 trials of ACEIs, and 34% (95% CI: 25%–42%) in 9 trials of CCBs.</td>
<td>• With the exception of the extra protective effect of BBs given shortly after a MI and the minor additional effect of CCBs in preventing stroke, all the classes of BP-lowering drugs have a similar effect in reducing CAD events and stroke for a given reduction in BP.</td>

| Herlitz J, et al., 2002 (142) 11862577 | Aim: To see effect of metoprolol vs. placebo on mortality and hospitalizations among pts with history of HTN and HF with reduced LVEF  
**Study type:** RCT  
**Size:** 1,747 pts | **Inclusion criteria:** NYHA class II–IV HF with LVEF ≤40% within 3 mo of enrollment; supine resting HR ≥68 bpm; stable clinical condition  
**Exclusion criteria:** Acute MI or UA within 28 d of randomization; indication or contraindication for treatment with BBs or drugs with beta-blocking properties; poor compliance; CABG surgery or PTCA in past 4 mo | **Intervention:**  
• Administration of metoprolol  
• 871 pts randomized to metoprolol  
**Comparator:**  
• Administration of placebo  
• 876 pts randomized to placebo | **1° endpoint:** At 1-y follow-up, compared with placebo, metoprolol reduced all-cause mortality 39% (95% CI: 16%–56%; p=0.002) and all-cause mortality or all-cause hospitalization 24% (95% CI: 11%–35%; p=0.0007)  
**1° Safety endpoint:** Early permanent cessation of drug was 12.5% for metoprolol and 15.9% for placebo (p=0.048); 21 pts on metoprolol and 35 pts on placebo had early cessation because of worsening | Relevant 2° endpoint: At 1-y follow-up, compared with placebo, metoprolol reduced CV death 41% (95% CI: 17%–57%; p=0.002), death from HF: 51% (95% CI: 1%–75%; p=0.042), sudden cardiac death 49% (95% CI: 21%–67%; p=0.002), all-cause mortality or HF hospitalization 28% (95% CI: 11%–42%; p=0.002), and cardiac death or nonfatal acute MI 44% (95% CI: 23%–60%; p=0.0003)  
**Study limitations and adverse events:** Early permanent cessation of drug was 12.5% for metoprolol and 15.9% for placebo (p=0.048); 21 pts on M and 35 pts on placebo had early cessation because of worsening HF; all-cause withdrawals were 22% less with metoprolol; (p=0.048); adverse events were 28% less with metoprolol (p=0.026); worsening HF was 41% less with metoprolol (p=0.056)  
**Summary:** In an RCT of pts with HF with reduced EF and a history of HTN, compared with placebo, metoprolol succinate reduced all-cause mortality and all-cause hospitalization |
| Packer M, et al., 2001 (140) 11386263 | Aim: To assess survival in severe dyspnea/exertion for 2 mo at least and left EF<25% despite | **Inclusion criteria:** HF pts with dyspnea/exertion for 2 mo at least and left EF<25% despite | **Intervention:** Carvedilol (1,156) | **1° endpoint:** Death from any cause 130 vs. 190 deaths (RR: 35%; p=0.002) | **Study stopped early (1.3 y follow-up) due to benefit on survival** |
### CAPRICORN

**Dargie HJ, et al., 2001 (141) 11356434**

**Aim:** To investigate outcomes after carvedilol after MI in pts with LV dysfunction.

**Study type:** RCT

**Size:** 1,959 pts

**Inclusion criteria:** Pts ≥ 18 y, MI within 3–21 d of entry, LVEF ≤ 40%, concurrent ACEI stable dose for at least 24 h, HF pts treated and controlled with ACEI and diuretics but not inotropes.

**Exclusion criteria:** SBP < 90 mm Hg, uncontrolled HTN, bradycardia, insulin-dependent DM, BBs not for HF, Beta-2 agonists, and steroids

**Intervention:** Carvedilol (975)

**Comparator:** Placebo (984)

**1° endpoint:** All-cause mortality or hospital admissions for CV issues

**Results:** 12% vs. 15%; RR: 23% (95% CI: 0.60–0.98; p=0.03)

No difference between groups for death or CV hospital admissions

• CV mortality, nonfatal MI reduced in the carvedilol group
• No difference between groups sudden death and admission due to HF

### Elkayam U, et al., 1990 (144) 2242521

**Aim:** To assess comparative efficacy and safety of nifedipine and ISDN alone and the combination for treating for chronic CHF.

**Inclusion criteria:** 18–75 y old HF pts, NYHA class II and III, LVEF<40%, clinically stable, maintenance dose of Digitalis and diuretics.

**Exclusion criteria:** Pregnancy, nursing, history of MI <1 mo before entry, valvular disease, angina, significant pulmonary,

**Intervention:** Nifedipine (21), ISDN (20), Nifedipine+ISDN (23)

**Comparator:** Placebo

**Endpoints and Results:**

• HF-worsening: 9 in Nifedipine group vs. 3 in ISDN group (p<0.001 vs. nifedipine, p<0.0001 vs. ISDN)

• Clinical deterioration discontinuation:

• In clinical deterioration nifedipine pts (8) vs. rest of the pts (No difference in LVEF or VO² max.)

• Although all the 3 drug regimens improved exercise capacity, nifedipine treatment alone or in combination resulted in clinical deterioration and worsening of CHF
<table>

Exclusion criteria:
- Inability to discontinue ACEI or ARB
- Known hypersensitivity or intolerance to ACEI or ARB
- Selected CVDs (congestive HF, hemodynamically significant valvular or outflow tract obstruction, constrictive pericarditis, complex congenital heart disease, syncopal episodes of unknown etiology <3 mo, planned cardiac surgery or PTCA <3 mo, uncontrolled HTN on treatment [e.g., BP >160/100 mm Hg], heart transplant recipient, stroke due to subarachnoid hemorrhage)
- Other conditions (significant renal artery disease, hepatic dysfunction, uncorrected volume or sodium depletion, 1° hyperaldosteronism, hereditary fructose intolerance, other major noncardiac illness or expected to reduce life expectancy or significant disability interfere with study participation, simultaneously taking another experimental drug, unable to provide written informed consent).

Composite outcome of death from CV causes, MI, stroke, or hospitalization for HF (RR: 1.01; 95% CI: 0.94–1.09 and RR: 0.99; 95% CI: 0.92–1.07, respectively)

Safety endpoint:
- Combination therapy was associated with greater risk of hyperkalemia than ramipril monotherapy (480 pts vs. 283 pts; p<0.001)
- Hypotensive symptoms were cited as reason for permanent discontinuing more in telmisartan vs. ramipril (RR: 1.54; p<0.001) and combination therapy vs. ramipril monotherapy (RR: 2.75; p<0.001)
- Renal impairment was more common in combination therapy vs. ramipril monotherapy (RR: 1.33; 95% CI: 1.22–1.44)

adverse events without an increase in benefit

| TOPCAT Pfeffer MA, et al., 2015 (161) | Aim: To investigate variation in pts and outcome in TOPCAT between pts from the Americas vs. Russia/Georgia Study type: Post-hoc analysis of prospective, double-blind, RCT Size: 3,445 pts | Inclusion criteria: NYHA class II–IV HF with LVEF ≤40% within 3 mo of enrollment; supine resting heart rate ≥68 bpm; stable clinical condition Exclusion criteria: Acute MI or UA within 28 d of randomization; indication or contraindication for treatment with BBs or drugs with beta-blocking properties; poor compliance; CABC surgery or PTCA in past 4 mo | Intervention: • Americas 886 on spironolactone • Russia/Georgia 836 on spironolactone • Spironolactone 15–45 mg daily Comparator: • Americas 881 on placebo • Russia/Georgia 842 on placebo • Placebo | 1st endpoint: Composite of CV death, aborted cardiac arrest, or HF hospitalization at 3.3 y follow-up was: Americas: 27.3% for spironolactone and 31.8% for placebo HR: 0.82; 95% CI: 0.69–0.98; p=0.026; Russia/Georgia 9.3% for spironolactone and 8.4% for placebo HR: 1.10; 95% CI: 0.79–1.51; p=0.58 1st Safety endpoint: • Doubling of serum creatinine: Americas: 17.8% for spironolactone and 11.6% for placebo HR: 1.60; 95% CI: 1.25–2.05; p<0.001 • Russia/Georgia 2.0% for S and 2.1% for p HR: 0.95; 95% CI: 0.49–1.85; p=0.89 • Creatinine >3.0 mg/dL Americas 9.8% for spironolactone and 9.1% for placebo HR: 1.10; 95% CI: 0.81–1.49; p=0.55 • Russia/Georgia 0.2% for spironolactone and 0.4% for placebo HR: 0.5; 95% CI: 0.09–2.75; p=0.43 • Hyperkalemia (potassium >5.5 mmol/L) Americas 25.2% for spironolactone and 8.9% for placebo OR: 3.46; 95% CI: 2.62–4.56; p<0.001 | Relevant 2nd endpoint: CV mortality: America 10.8% for spironolactone and 14.4% for placebo HR: 0.74; 95% CI: 0.57–0.97; p=0.027; Russia/Georgia 7.7% for spironolactone and 5.8% for placebo HR: 1.31; 95% CI: 0.91–1.90; p=0.15. Aborted cardiac arrest: NS between groups. HF hospitalization: 20.8% for spironolactone and 24.5% for placebo HR: 0.82; 95% CI: 0.67–0.99; p=0.042; Russia/Georgia 2.6% for spironolactone and 3.4% for placebo HR: 0.76; 95% CI: 0.44–1.32; p=0.327; Recurrent HF: 361 events for spironolactone and 438 events for placebo (IRR: 0.75; 95% CI: 0.58–0.96; p=0.024) Russia/Georgia 33 events for spironolactone and 37 events for placebo (IRR: 0.83; 95% CI: 0.42–1.62; p=0.58) All-cause mortality: NS between groups in Americas and Russia/Georgia. All-cause hospitalization: NS between groups in Americas and Russia/Georgia. MI: NS between groups; Stroke: NS between groups | Study limitations and adverse events: The pts enrolled in Russia/Georgia in the TOPCAT trial did not demonstrate either the expected morbidity and mortality associated with symptomatic HF or
### Summary

In pts with HF with preserved EF, spironolactone reduced the 1° endpoint of composite of CV death, aborted cardiac arrest, or HF hospitalization in the Americas group but not in the Russia/Georgia group. The pts enrolled in the Russia/Georgia group did not demonstrate either the expected morbidity and mortality associated with symptomatic HF with preserved EF or most pharmacological responses to spironolactone.

### Relevant 2° endpoint

CV mortality and nonfatal hospitalized HF was reduced 30% (p=0.002) by antihypertensive drug therapy

### Antihypertensive drug therapy reduced HF, 64% (p<0.001) all-cause mortality 21% (p=0.02), and CV death 23% (p=0.06)

</table>
| MDRD Klahr S, et al., 1994 (169)     | **Aim**: To determine whether restricted protein intake or tighter HTN control would delay progression of CKD  
  **Study type**: Randomized management to low or usual BP goal and usual, low or very low protein intake  
  **Size**:  
  • Total n=840: Study 1 n=585; Study 2 n=255  
  • Mean follow-up 2.2 y  
  • Mean MAP, mm Hg (SD): Study 1: 98 (11); Study 2: 98 (11)  
  • Mean SBP, mm Hg (SD): Study 1: 131 (18); Study 2: 133 (18)  
  **Inclusion criteria**: Adults 18–70 y, with renal insufficiency (serum Cr 1.2–7.0 mg/dL in women and 1.4–7.0 mg/dL in men or CrCl <70 mL/min per 1.73 m²) and MAP≤125 mm Hg (normotensives included)  
  **Exclusion criteria**: Pregnancy, body weight <80% or >160% of standard, DM requiring insulin, urine protein >10 g/d, history of renal transplant, chronic medical conditions, doubts regarding compliance.  
  **Intervention**:  
  • Study 1 included subjects with GFR 25–55 mL/min 1.73 m² (n=585):  
    • Study 2 included subjects with GFR 13–24 mL/min 1.73 m² (n=255)  
  • Low MAP goal ≤92 mm Hg for those 18–60 y; ≤98 for those ≥61 y  
  • Usual: MAP goal ≤107 mm Hg for those 18–60 y; ≤113 for subjects ≥61 y  
  • 2 studies:  
    Study 1: above BP goals plus usual or low protein diet (1.3 or 0.58 g protein per kg of body weight/d)  
    Study 2: above BP goals plus low or very low protein diet (0.58 or 0.28 g per kg/d)  
  • Between group difference in MAP, mm Hg 4.7; p<0.001  
  **1° endpoint**: Rate of decline in GFR, mL/min (95% CI)  
  • Study 1  
    From baseline to 4 mo  
    Low: 3.4; 95% CI: 2.6–4.1  
    Usual: 1.9; 95% CI: 1.1–2.7  
    p=0.010  
    4 mo to study end,  
    Low: 2.8; 95% CI: 2–3.3  
    Usual: 3.9; 95% CI: 3.3–4.5  
    p=0.006  
    Baseline to 3 y,  
    Low: 10.7; 95% CI: 9.1–12.4  
    Usual: 12.3; 95% CI: 10.6–14.0  
    p=0.18  
  • Study 2  
    From baseline to end of study,  
    Low: 3.7; 95% CI: 3.1–4.3  
    Usual: 4.2; 95% CI: 3.6–4.9  
    p=0.28  
    ESRD or death:  
    • Study 2  
      RR for low vs. usual: 0.85; 95% CI: 0.60–1.22  
      p=NR  
  **Limitations**:  
  • Drug therapy was not randomized. Recommended ACEI ± diuretic then CCB and others. More subjects in the low BP goal groups received ACEIs (48%, 51% also reported elsewhere) compared to the usual BP goal group (28%, 32% also reported e/w) (not noted in 1° manuscript but reported in Peterson JC, et al., 1995 (170)).  
  1.9% study 1, 1.2% study 2 lost to follow-up.  
  • Rate of GFR decline was slower than expected in the control groups and was not constant.  
  **Summary**: No significant benefits overall from either low protein or lower BP target. There was a significant interaction between baseline urinary protein excretion and BP interventions (p=0.01) indicating that low BP was of benefit to subjects with >1 g proteinuria with slower progression of loss of GFR |
| REIN-2 | **Aim:** To determine whether intensive BP control will achieve further renoprotection (delayed progression to ESRD) compared to standard BP control in pts with chronic nephropathies | **Inclusion criteria:**  
- Adults, age 18–70 y, with nondiabetic nephropathy, persistent proteinuria (urinary protein excretion >1 g/24 h for ≥3 mo) and not on ACEIs in previous 6 wk  
- Pts with proteinuria 1–3 g/24 h included if CrCl <70 mL/min/1.73 m²  
- For overall population, mean SBP, mm Hg (SD):  
  - Intensive: 137.0 (16.7)  
  - Conventional: 136.4 (17.0)  
- For overall population, mean DBP, mm Hg (SD):  
  - Intensive: 84.3 (9.0)  
  - Conventional: 83.9 (10.4) | **Intervention:**  
- Intensive: BP goal <130/80 mm Hg  
- Conventional: DBP goal <90 mm Hg, irrespective of SBP  
- For baseline proteinuria subgroups, result BP values NR  
- For the overall population, achieved BP, mm Hg (SD):  
  - Intensive: 129.6/79.5 (10.9/5.3)  
  - Conventional: 133.7/82.3 (12.6/7.1)  
- Change in BP, mm Hg:  
  - Intensive: -7.4/-4.8  
  - Conventional: -2.7/-1.6  
- BP difference between groups, mm Hg:  
  - Intensive: 4.1/2.8  
  - Conventional: 0.8/2.8  | **1° endpoint:**  
- Time to ESRD; over 36 mo follow-up, median 19 mo  
- 1° outcome: ESRD in pts with baseline proteinuria 1–3 g/24 h  
  - HR (95% CI): 1.06 (95% CI: 0.51–2.20)  
  - p=0.89  
- ESRD in pts with baseline proteinuria >3 g/24 h  
  - HR (95% CI): 1.09 (95% CI: 0.55–2.19)  
  - p=0.81  
- 23% of intensive and 20% of conventional control groups progressed to ESRD.  
- Median rate of GFR decline, mL/min/1.73 m²/mo (IQR) in pts with baseline proteinuria <3 g/24:  
  - Intensive: 0.18 (95% CI: 0.03–0.49)  
  - Conventional: 0.39 (95% CI: 0.03–0.98)  
  - p=0.39 | **Limitations:** The study was stopped at the 1st interim analysis for futility. Median time 19 mo  
**Summary:** In pts with non-DM proteinuric nephropathies receiving background ACEI therapy, no additional benefits from further BP reduction by felodipine could be shown. Dihydropyridine CCBs do not offer additional renoprotection to ACEIs or ARBs.

</tbody>
</table>

**Safety endpoint:**
- Acute and chronic rate of change in GFR (slope):
  - NS for chronic and total slope in subgroup analyses by baseline proteinuria strata
  - Acute slope: p=0.08 for interaction
  - Total slope: p=0.04 for interaction
  - Chronic slope: p=0.16 for interaction
- Clinical composite outcome: includes reduction in GFR by 50% or by 25 mL/min/m², ESRD, death, NS in subgroup analyses by baseline proteinuria strata; p=0.007 for interaction
- For above outcomes, trends favored the lower BP goal over the usual goal in participants with higher baseline proteinuria and opposite trends in participants with little or no proteinuria. Within each drug group, risk reductions for any 2° clinical outcome of the low vs. usual BP goal were not significantly different between pts with baseline urine protein to creatinine ratio ≤0.22 and >0.22 (p=NS)

**Limitations:**
- Post-hoc analysis, effects on GFR may have been obscured by early rise and later fall with amlodipine, follow-up only 3–6.4 y, many comparisons so risk for type I error, unable to test ACEI – DHP CCB combination.

**Summary:**
- BP effect was similar among drug groups for GFR slope and main clinical composite.

- Low, Ramipril: 96.90 (13.6)
- Usual, Ramipril: 95.12 (15.3)

**Safety endpoint:**
- ESRD alone, Amlodipine, Low vs. Usual Goal: RR: 54%; 95% CI: 8–77; p=0.028
- Metoprolol, Low vs. Usual Goal RR: 11%; 95% CI: -60–50; p=0.70
- Ramipril, Low vs. Usual Goal RR: -65%; 95% CI: -195–8; p=0.09; p for interaction=0.021
- Death alone (prior to dialysis), Amlodipine, Low vs. Usual Goal: RR: 48%; 95% CI: -59–83; p=0.25
- Metoprolol, Low vs. Usual Goal RR: -1; 95% CI: -110–5; p=0.97
- Ramipril, Low vs. Usual Goal RR: 21%; 95% CI: -92–67; p=0.61; p for interaction=0.61

**BP effect differed among drug groups for composite of ESRD or death and ESRD alone.**
- Higher event rates for amlodipine and usual BP goal compared with other groups.
- Low BP goal associated with reduced risk of ESRD or death and ESRD for amlodipine but not for other drug groups (in the absence of ACEI treatment).
| Norris K, et al., 2006 (174) 17059993 | **Aim:** Compared effect of treatment on CV event rate during mean follow-up of 4.1 y by drug class and level of BP control. Determined baseline factors that predict CV outcomes.  
**Study type:** Randomized 3×2 factorial trial  
Measured GFR with iothalamate  
**Size:** 1,094 | **Inclusion criteria:**  
- Adult African Americans, 18–70 y, with HTN (DBP ≥95) and GFR of 20–65 mL/min/1.73 m², no DM  
- Mean MAP, mm Hg: 114 (16)  
- Mean SBP, mm Hg: 150 (24)  
- Mean DBP, mm Hg: 96 (14)  
**Exclusion criteria:** N/A | **Intervention:**  
- Achieved SBP/DBP, mm Hg (SD)  
  - Low: 128/78  
  - Usual: 141/85  
  - SBP/DBP change, mm Hg  
  - Low: -23/-19  
  - Usual: -8/-9  
  - Achieved mean BP difference between groups, mm Hg  
  - SBP: 15  
  - DBP: 10  
  - Comparator: N/A  

| **1° endpoint:**  
- Number of deaths before ESRD, n of events  
  - Low: 38  
  - Usual: 47; p=NR  
- Major CAD events, n of events (rate per person-y)  
  - Low: 19 (0.008)  
  - Usual: 23 (0.010); p=NS  
- Stroke events, number of events (rate per person-y)  
  - Low: 26 (0.011)  
  - Usual: 29 (0.013); p=NS  
- HF events, n of events (rate per person-y)  
  - Low: 27 (0.012)  
  - Usual: 23 (0.010)  
  - CV composite outcome, n of events (rate per person-y)  
  - Low: 71 (0.032)  
  - Usual: 78 (0.035); p=NS  
- Composite outcome or ESRD, n of events (rate per person-y)  
  - Low: 143 (0.064)  
  - Usual: 159 (0.072)  
  - Overall rate of CV events, n of events (rate per person-y)  
  - Low: 108 (0.048)  
  - Usual: 94 (0.042); p=NS  
- CV death, n of events (rate per person-y)  
  - Low: 16 (0.007)  

| **Limitations:**  
- Limited power, only 202 CV events – low incidence. CV outcomes were 2° endpoints of high priority (prespecified).  
- >50% had a history of heart disease at entry, 40% with LVH by ECG. 1/3 smokers, almost 50% had income <15K.  
**Summary:**  
- CV outcome rate was not related to randomized interventions, either drug or BP target.  
- 7 baseline risk factors were independently associated with increased risk for CV composite outcome in multivariable analyses after controlling for age, sex, baseline GFR, baseline proteinuria: PP, duration of HTN, protein/creatinine ratio, urine sodium-potassium ratio and annual income <15,000. |
| Amlodipine Versus Enalapril in Renal Failure (AVER trial) Esnault VL, et al., 2008 (175) 18405787 |
|--------------------------------------------------|--------------------------------------------------|
| **Aim:** To compare GFR decline in nondiabetic, nonnephrotic adults with HTN and estimated CrCl 20–60 mL/min/1.73 m² when randomized to a CCB (amlodipine, 5–10 mg/d) or an ACEI (enalapril, 5–20 mg/d). |
| **Study type:** RCT |
| **Size:** Amlodipine: 132 Enalapril: 131 |
| **Inclusion criteria:** |
| ● 18–80 y |
| ● CrCl 20–60 mL/min/1.73 m² (Cockcroft-Gault) |
| ● Nondiabetic |
| ● Enrollment confirmed at end of 4-wk placebo run-in if sitting DBP between 90 and 119 mm Hg |
| ● Mean SBP, mm Hg (SD): |
| Amlodipine: 165.1 (15.4) |
| Enalapril: 165.2 (16.6) |
| ● Mean DBP, mm Hg (SD): |
| Amlodipine: 102.0 (6.7) |
| Enalapril: 102.5 (7.1) |
| ● Mean serum Cr, mg/dL (SD): |
| Amlodipine: 2.00 (0.8) |
| Enalapril: 2.05 (0.7) |
| **Exclusion criteria:** |
| ● Nephrotic proteinuria |
| ● 2° or malignant HTN (DBP >120 mm Hg) |
| ● A major CV event within 3 mo |
| ● Angina pectoris |
| ● Congestive heart disease (NYHA II-IV) |
| ● Uncontrolled arrhythmias |
| ● II-III AV block |
| ● Need for serious steroids, NSAIDS or cytotoxic drugs |
| **Intervention:** |
| ● Amlodipine: 5–10 mg/d |
| ● Enalapril: 5–20 mg/d |
| Therapy initiated with amlodipine 5 mg/d or enalapril 5 mg/d. Drugs up-titrated to amlodipine 10 mg/d or enalapril 20 mg/d at wk 8 and 12 if DBP >90 mm Hg. After 18 wk, if maximal tolerated dose of study drug did not decrease BP to target, add on anti-HTN treatments were the following: atenolol (50–100 mg/d), loop diuretics (furosemide 20–500 mg/d or torsemide, 5–200 mg/d), alpha blockers (prazosin, 2.4–5 mg/d or doxazosin, 1–16 mg/d) and centrally acting drugs (rilmenidine (1–2 mg/d or methyldopa, 250–500 mg/d). |
| **BP goal:** |
| Amlodipine: <130/85 mm Hg |
| Enalapril: <130/85 mm Hg |
| **Duration of treatment:** Median follow-up 2.93 y in amlodipine group; 2.95 y in enalapril group |
| **1° endpoint:** Change in GFR from baseline to final assessment |
| **2° Outcome:** Clinical composite of renal replacement therapy, discontinuation due to deterioration of renal function, 50% decrease in GFR, doubling of serum Cr, hospitalization for transient renal failure. "Other 2° outcome measures" included: changes in serum Cr, sitting DBP and SBP, heart rate, total and HDL cholesterol, 24-h urinary protein excretion, ambulatory BP monitoring, and safety measures. Composite Outcomes: 2° clinical composite |
| **Safety endpoint:** Proteinuria subgroup, >1 g/d: protein excretion rate decreased significantly in pts taking enalapril plus diuretic (median -270 mg/d; p<0.001) but not in pts taking amlodipine plus diuretic (-25 mg/d) at last obs |
| **Summary:** |
| ● No difference in GFR change or serum creatinine at trial end |
| ● Last observation: mean change in GFR, mL/min/1.73 m² Amlodipine -4.92, Enalapril -3.98; p=NS |
| ● Last observation: mean change in Serum Cr from baseline (mg/d) Amlodipine +0.57, Enalapril +0.47; p=NS |
| ● No difference in composite 2° endpoints. |
| ● Mean BP (mm Hg): baseline to last observation Amlodipine 164.8/101.8 to 140.1/85.4, delta -24.7/16.4 Enalapril 165.0/102.5 to 140.3/86.4, delta -24.7/16.1 |
| Usual: 15 (0.006); p=NS |

**Summary:**
- No difference in GFR change or serum creatinine at trial end.
- Last observation: mean change in GFR, mL/min/1.73 m², Amlodipine -4.92, Enalapril -3.98; p=NS.
- Last observation: mean change in serum Cr from baseline (mg/d), Amlodipine +0.57, Enalapril +0.47; p=NS.
- No difference in composite 2° endpoints.
- Mean BP (mm Hg): baseline to last observation, Amlodipine 164.8/101.8 to 140.1/85.4, delta -24.7/16.4, Enalapril 165.0/102.5 to 140.3/86.4, delta -24.7/16.1.
### ESPIRAL
Marin R, et al., 2001 (176)

<p>| <strong>Aim:</strong> | To investigate in a random comparison the capacity of an angiotensin converting enzyme inhibitor (fosinopril), and that of a long-acting dihydropiridine (nifedipine GITS) to modify the decay in renal function in pts with primary renal disease, exhibiting a progressive increase in serum Cr during the previous 2 y. |
| <strong>Study type:</strong> | Randomized open label trial |
| <strong>Size:</strong> | 241 Nifedipine GITS: 112 Fosinopril: 129 |
| <strong>Inclusion criteria:</strong> | - 18–75 y - Serum Cr between 1.5 and 5 mg/dL (133–442 µmol/l) - HTN defined as BP &gt;140/90 mm Hg or by the use of antihypertensive agent(s) - Proven progression of chronic renal failure in the previous 2 y, defined by increase by &gt;25% or &gt;0.5 mg/dL (44.2 µmol/l) in serum Cr - Mean SBP, mm Hg (SD): Nifedipine GITS: 157.5 (20) Fosinopril: 155 (17) - Mean DBP, mm Hg (SD): Nifedipine GITS: 96 (11) Fosinopril: 96 (8) |
| <strong>Exclusion criteria:</strong> | - DM - Previous recent history of CVD (stroke, MI, or HF) - Taking concomitant medications that could limit the ability of pts to comply with protocol requirements |
| <strong>Intervention:</strong> | - Nifedipine GITS: 30–60 mg QD - Fosinopril: 10–30 mg QD - Drugs added in step-wise fashion to achieve BP goal. |
| <strong>1° endpoint:</strong> | - 1° Outcome: Time elapsed until serum Cr values doubled, or the need to enter a dialysis program |
| <strong>Safety endpoint:</strong> | N/A |
| <strong>Limitations:</strong> | - SBP was 4–6 mm Hg lower with ACEI which may have impacted improved outcomes. Still positive effects remained from fosinopril after adjusted for BP levels. - Sodium restriction may have favored the ACEI group. |
| <strong>Summary:</strong> | - Renal survival was significantly better if fosinopril used as first agent, unrelated to the primary renal disease. - Proteinuria decreased by 57% in the fosinopril group and increased by 7% in the nifedipine GITS group while BP control did not differ between treatment groups for DBP. - 3-y follow-up Doubling of serum Cr or entering dialysis N (%) Nifedipine GITS 40 (36%) Fosinopril 27 (21%) OR: 0.47 (0.26–0.84); p=0.01 - Decrease in SBP, mm Hg (SD) Nifedipine GITS 14.0 (SD) Fosinopril 14.9 (11.8) |</p>

### 2008 (178) RAAS by aliskiren 300 mg/d added to maximal dose losartan 100 mg/d and optimal HTN therapy

| Study type: | RCT, double-blinded, duration was 6 mo |
| Size:       | 805 entered open label, 599 randomized, 524 completed. |
| Inclusion criteria: | and DM-2 and nephropathy (early morning alb/creat >300 mg/g or >200 mg/g in on RAAS blocker already |
| Exclusion criteria: | Non-DM kidney disease, >3,500 mg/g alb/Cr ratio, eGFR, 30 mL/min/BSA, chronic urinary tract infections, baseline serum potassium >5.1, severe HTN, major CVD in prior 6 mo |
| Comparator: | All on losartan, aliskiren or placebo added |
| Safety endpoint: | ● 2º: decline in eGFR, development of renal dysfunction (serum creatinine >176.8 micromol/l (2.0 mg/dL) |
| Summary: | ● Outcome was degree of albuminuria. Aliskiren reduced urinary alb/creat ratio by 20% (95% CI 9–30; p<0.001) |
|           | ● From post hoc analysis: Antiproteinuric effects consistent across CKD stages (19%, 22%, and 18% for stages 3, 2, and 1). For CKD 3, renal dysfunction more frequent in placebo group (29.3 vs. 13.6%; p=0.032) |
|           | ● No differences in deaths or acute renal failure by treatment group (0.7% in both) |

### VA NEPHRON-D

Fried LF, et al., 2010 (124)

| Aim: | To test the efficacy of the combination of losartan with lisinopril as compared with standard treatment with losartan alone in slowing the progression of proteinuric diabetic kidney disease |
| Study type: | RCT, multi-center, double-blind |
| Size: | 1448 were randomized |
| Inclusion criteria: | Pts without adverse events on full dose losartan DM-2, eGFR 30–89.9 mL/min/1.73 m² by 4 variable MDRD formula, urinary albumin/creatinine ratio of ≥300 in a random sample |
| Intervention: | ● Pts with DM-2 already taking losartan 100 mg/d with albumin to creatinine ratio of ≥300 were randomized to either lisinopril 10–40 mg/d or placebo. ● 132 1º endpoints in the combination therapy group; No benefit to mortality or CV events. Combination therapy increase risk of hyperkalemia 6.3 events/100 person-y vs. 2.6 events/100 person-y (p<0.001) and acute kidney injury 12.2 vs. 6.7 events/100 person-y (p<0.001) |
| 1º endpoint: | First occurrence of a change in eGFR (a decline of ≥30 mL/min/1.73 m² if initial GFR ≥60 or a decline of ≥50% if initial eGFR <60, ESRD or death |
| Safety endpoint: | mortality, hyperkalemia, acute kidney injury |
| Summary: | Study stopped early due to safety concerns. Combination of ACEI and ARB was associated with increased risk of adverse events among pts with diabetic nephropathy |

<tr>
<td>Upadhyay A, et al., 2011 (179)</td>
<td>Aim: To summarize trials comparing lower vs. higher BP targets in pts with CKD; focus on proteinuria as an effect modifier</td>
<td><strong>Inclusion criteria:</strong> &gt;50 pts/group, 1 yr follow-up, outcomes of death, kidney failure, CV events, change in kidney function, number of antihypertensive agents, adverse events. 3 trials (MDRD, AASK, REIN-2; 8 reports)</td>
<td><strong>Results:</strong> Overall trials did not show that BP target of &lt;125/75–130/80 is more beneficial than a target of &lt;140/90. Lower quality evidence suggests a low target may be beneficial in subgroups with proteinuria &gt;300–1,000/d</td>
<td><strong>Limitations:</strong> No pts with DM-1 included. Duration (mean follow-up 2–4 yr) may be too short to detect differences in clinically important outcomes. Reporting of adverse events not uniform. <strong>Summary:</strong> Available evidence is inconclusive but does not prove a BP target &lt;130/80 improves clinical outcomes more than a target of &lt;140/90 in adults with CKD.</td>
</tr>
<tr>
<td>Lv, et al., 2013 (127)</td>
<td><strong>Aim:</strong> To assess the renal and CV effects of intensive BP lowering in people with CKD</td>
<td><strong>Inclusion criteria:</strong> • Randomized trials of pts with CKD assigned to different target BP that reported kidney failure and CV events. • 11 trials on 9,287 pts with CKD and 1,264 kidney failure events (doubling of serum creatinine, 50% decline in GFR or ESKD) • Included AASK, REIN-2, MDRD, Wuhl (children), Toto, Schrier plus 5 trials with CKD subgroups, also included the late nonrandomized follow-up studies for AASK and MDRD • BP targets varied substantially between trials. 2 trials targeted mean BP &lt;92 mm Hg for the intensive treatment arm, and 107 mm Hg in the standard treatment arm. 1 trial aimed for BP&lt;130/80 mm Hg vs. a DBP of 90 mm Hg, 1 study targeted &lt;120/80 mm Hg vs.</td>
<td><strong>Results:</strong> Compared with standard regimens, more intensive BP lowering reduced risk of composite endpoint HR: 0.82; 95% CI: 0.68–0.98, and ESKD HR: 0.79; 95% CI: 0.67–0.93. Effect was modified by proteinuria (p=0.006) and markers of trial quality. Intensive BP lowering reduced the risk of kidney failure HR: 0.73; 95% CI: 0.62–0.86 but not in pts without proteinuria at baseline HR: 1.12; 95% CI: 0.67–1.87. No clear effect on CV events or death.</td>
<td><strong>Limitations:</strong> All trials used open label, in 2 pts were blinded, substantial variability in design quality. There was substantial variability in BP targets by MAP, systolic and DBP or only DBP. Most trials did not include pts with diabetic kidney disease. <strong>Summary:</strong> • Renal outcomes: 7 trials (N=5,308) recorded a total of 1,264 kidney failure events. A -7.7 mm Hg difference in SBP and a -4.9 mm Hg difference in DBP seen between treatment arms. Overall, a more intensive regimen reduced risk of composite kidney failure events by 17% HR: 0.82; 95% CI: 0.68–0.98, reduced the risk of ESKD alone by 18% (pooled HR for composite outcomes: 0.79; 95% CI: 0.67–0.93). • Intensive BP lowering had no effect on kidney failure in pts who did not have proteinuria (3 trials involving 1,218 pts HR: 1.12; 95% CI: 0.67–1.87), but it did reduce the risk of progressive kidney failure by 27% (5 trials involving 1,703 pts HR: 0.73; 95% CI: 0.62–0.86 in people who did have proteinuria at baseline.</td>
</tr>
</tbody>
</table>
135–140/85–90 mm Hg, and 4 studies had DBP<75–80 mm Hg vs. from 80–90 mm Hg. A trial involving pediatric pts targeted a 24-h mean BP<the 50th percentile, compared with the 50th to 95th percentiles in the control group. 2 trials had more liberal targets for intensive treatment (<140–150 mm Hg systolic, 85 mm Hg diastolic).

### CV outcomes:
Major CV events reported in 5 trials (472 CV events in 5,308 pts with CKD). Intensive BP lowering did not reduce risk of CV events in pts with CKD, but the CIs remained wide RR: 1.09; 95% CI: 0.83–1.42. 6 trials reported stroke outcomes (197 events in 5,411 pts), 5 trials reported MI (138 events in 4,317 pts), and 5 trials reported HF (118 events in 5,308 pts). They saw no clear effect of intensive treatment on any of these vascular outcomes.

### Death:
10 trials involving 6,788 participants reported 846 deaths. There was no clear effect of intensive BP lowering on risk of all-cause death RR: 0.94; 95% CI: 0.84–1.05) or CV death RR: 1.20; 95% CI: 0.82–1.75.

### Jafar TH, et al., 2003 (180)

**Aim:** To determine the levels of BP and urine protein excretion associated with lowest risk for progression of CKD during antihypertensive therapy with and without ACEIs.

**Study type:** 11 RCTs in pts with predominantly nondiabetic kidney disease

**Size:** 1,860 pooled in pt level meta-analysis; mean duration of follow-up 2.2 y

**Inclusion criteria:**
- Pt-level meta-analysis using data from the AIPRD Study Group database to assess relationships among pts with nondiabetic kidney disease across a wide range of urine protein excretion values during antihypertensive therapy with and without ACEIs.
- The AIPRD Study Group database included 1,860 pts with nondiabetic kidney disease enrolled in 11 RCTs of ACEIs to slow the progression of kidney disease. The database contained information on BP, urine protein excretion, serum creatinine, and onset of kidney failure during 22,610 visits.
- Included only randomized trials (with a minimum 1 y follow-up) that compared the effects of antihypertensive regimens that included ACEIs with the effects of regimens that did not include ACEIs. HTN or decreased kidney function was required for entry into all studies.

**Exclusion criteria:** Common to all studies: acute kidney failure, treatment with immunosuppressive meds, clinically significant chronic HF, obstructive uropathy, renal artery stenosis, active systemic disease, DM-1, history of transplantation, history of allergy to ACEIs.

**1° endpoint:** Progression of CKD defined as doubling of serum creatinine or onset of kidney failure

**Results:** Kidney disease progression documented in 311 pts, 124 (13.2%) in the ACEI group and 187 (20.5%) in the control group (p=0.001). 176 (9.5%) developed kidney failure: 70 (7.4%) in the ACEI group and 106 (11.6%) in the control group (p=0.002). SBP of 110–129 mm Hg and urine protein excretion <2.0 g/d were associated with lowest risk for kidney disease progression. ACEI beneficial after adjustment for BP and urine protein excretion (RR: 0.67; 95% CI: 0.53–0.84). The increased risk for kidney progression at higher SBP levels was greater in pts with urine protein excretion >1.0 g/d (p<0.006).

**Limitations:** Studies included were not designed to assess the effect of lowering BP and urine protein excretion on kidney disease progression.

**Conclusions:** Although reverse causation cannot be excluded with certainty, SBP goal between 110 and 129 mm Hg may be beneficial in pts with urine protein excretion >1.0 g/d. SBP <110 mm Hg may be associated with higher risk for kidney disease progression.
### 2017 Hypertension Guideline Data Supplements

| Giatras I, et al., 1997 (181) 9273824 | **Aim:** To use meta-analysis to assess effects if ACEIs on development of ESRD in nondiabetic pts.  
**Study type:** Meta-analysis  
**Size:** 1,594 pts from 10 studies | **Inclusion criteria:** All randomized studies comparing ACEIs with other antihypertensive agents, with at least 1 y of follow-up  
**Exclusion criteria:** Studies of diabetic renal disease and renal transplants were excluded.  
**Results:**  
- Among 806 pts receiving ACEIs, 52 (6.4%) developed ESRD and 17 (2.1%) died.  
- In 788 controls, 72 (9.1%) developed ESRD and 12 (1.5%) died. The pooled RR were 0.70; 95% CI: 0.51–0.97 for ESRD and 1.24; CI: 0.55–2.83 for death.  
- The decreases in weighted mean systolic and DBPs during follow-up were 4.9 and 1.2 mm Hg greater, respectively, in the pts who received ACEIs.  
**Limitations:** Included studies through 5/1996, published (7) and nonpublished (3) study results. Did not require that pts have HTN or renal insufficiency at baseline. Did not report results by severity of proteinuria related to the diseases included many of which are not characterized by proteinuria.  
**Summary:** ACEIs are more effective than other antihypertensive agents in reducing the development of end-stage nondiabetic renal disease, and they do not increase mortality. It could not be determined whether this beneficial effect is due to the greater decline in BP or to other effects of ACE inhibition. |

| ONTARGET Investigators, et al., 2008 (126) 18378520 | **Aim:** Evaluate whether use of an ARB was noninferior to ACEI, and whether the combination was superior to ACE alone in the prevention of vascular events in pts with CVD or DM but not HF.  
**Study type:** Multi-center, double-blind, RCT  
**Size:** 25,620 pts | **Inclusion criteria:**  
- ≥55 y  
- Coronary, peripheral, or cerebrovascular disease or DM with end-organ damage  
**Exclusion criteria:**  
- Inability to discontinue ACEI or ARB  
- Known hypersensitivity or intolerance to ACEI or ARB  
- Selected CVDs (congestive HF, hemodynamically significant valvular or outflow tract obstruction, constrictive pericarditis, complex congenital heart disease, syncopal episodes of unknown etiology <3 mo, planned cardiac surgery or PTCA <3 mo, uncontrolled HTN on treatment [e.g., BP >160/100 mm Hg], heart transplant recipient, stroke due to subarachnoid hemorrhage)  
- Other conditions (significant renal artery disease, hepatic dysfunction, uncorrected volume or sodium depletion,  
**Intervention:** Ramipril 10 mg daily (n=8,576)  
**Comparator:**  
- Telmisartan 80 mg daily (n=8,542)  
- Combination of telmisartan and ramipril (n=8,502)  
**1° endpoint:** After a median follow-up of 56 mo, there was no difference between ramipril vs. telmisartan or combination therapy vs. ramipril in the 1° composite outcome of death from CV causes, MI, stroke, or hospitalization for HF RR: 1.01; 95% CI: 0.94–1.09 and RR: 0.99; 95% CI: 0.92–1.07, respectively  
**Safety endpoint:**  
- Combination therapy was associated with greater risk of hyperkalemia than ramipril monotherapy (480 pts vs. 283 pts; p<0.001)  
- Hypotensive symptoms were cited as reason for permanent discontinuing more in telmisartan vs. ramipril RR: 1.54; p<0.001 and combination therapy vs. ramipril monotherapy RR: 2.75; p<0.001  
- Renal impairment was more common in combination therapy vs. ramipril monotherapy RR: 1.33; 95% CI: 1.22–1.44. |

</table>
| Cross NB, et al., 2009 (187) 19688343| **Study type:** Comparative assessment by drug class using RCTs and quasi-RCTs lasting at least 2 wk in kidney transplant pts  
**Size:**  
- 60 studies, 3,802 pts, most taking cyclosporine based immunosuppression  
- 29 studies (n=2,262) compared CCB to placebo, 10 (n=445) ACEI to placebo, 7 (n=405) CCB to ACEI | **Inclusion criteria:** 21 studies for HTN, 6 for erythrocytosis, 2 CAN, 2 LVH, 30 not specified  
**Exclusion criteria:** N/A | **1° endpoint:** To assess comparative effects of antihypertensive agents in kidney transplant pts  
**Results:** Used random effects meta-analysis, risk ratios for dichotomous outcomes and MD for continuous outcomes, both with 95% CI. Stratified analyses and meta-regression to investigate heterogeneity.  
- CCBs vs. placebo or no treatment had strongest results: improved GFR MD: 4.45 mL min (95% CI: 2.22–6.68), reduced graft loss RR: 0.75, (95% CI: 0.57–0.99).  
- ACEI vs. placebo inconclusive for GFR MD: -8.07 mL/min (95% CI: -18.57–2.43) and variable for graft loss.  
- Compared to CCB, ACEI decreased GFR MD: -11.48 mL/min; 95% CI: -5.75– -7.21), proteinuria MD: -0.28 g/24 h (95% CI: -0.47– -0.10), also reduced hemoglobin MD: -12.96 g/L (95% CI: -5.72– -10.21) and increased hyperkalemia RR: 3.74 (95% CI: 1.89– 7.43). Graft loss data were inconclusive.  
- CCB may be preferred as first line for HTN after kidney transplant. ACEI may have some detrimental effects. There were not enough studies with other agents. |
| Jennings DL, et al., 2008 (188) 18094340 | **Study type:** Literature review  
**Size:** 5 studies with 3 reporting safety endpoints and 2 reporting clinical efficacy endpoints | **Inclusion criteria:** Studies using either ACEI or ARB initiated within the first 12 wk after renal transplant | **1° endpoint:** Safety or efficacy  
**Results:**  
- No significant increase in serum creatinine or potassium after up to 9 mo Rx  
- Early initiation of ACEI may be more effective than BB in reducing LVH and proteinuria after 24 mo treatment | **Conclusion:** Reasonable to consider RAAS inhibitors as first-line treatment in pts with HTN and compelling indications i.e., DM, HF in first 12 wk after renal transplant. |
| Ninomiya T, et al., 2013 (189) 24092942 | **Aim:** To define CV effects of lowering BP in pts with CKD  
**Study type:** | **Inclusion criteria:** Had to meet 1 of the following criteria: Pts randomized to a BP-lowering drug/regimen or a control group (placebo or less intensive BP lowering regimen) or pts randomized | **Results:** Compared with placebo, BP lowering regimens reduced the risk of major CV events by about a sixth per 5 mm Hg reduction in SBP in individuals with (HR: 0.83; 95% CI)  
**Limitations:**  
- Limited numbers with CKD and most were stage 3a:  
- There were 121,995 pts (80%) with eGFR ≥60 mL/min/1.73 m² (mean eGFR 81 (SD 17) |  

© 2017 American College of Cardiology Foundation and American Heart Association, Inc. 140
Meta-analysis of RCTs
Individual pt data available for 23 trials, with summary data from another 3. Meta-analysis was performed according to baseline kidney function.

**Size:** 26 trials (152,290 pts), including 30,295 pts with reduced eGFR, defined as eGFR <60 mL/min/1.73 m².

### Inclusion criteria:
- Between regimens based on different classes of drugs to lower BP. Trials required to have at least 1,000 pt-y of planned follow-up in each randomized arm and not to have presented or published their main results before finalization of the overview protocol in July 1995.
- **Exclusion criteria:** Trials prior to July 1995.

**Intervention:** Ramipril 10 mg daily (n=8,576)
**Comparator:**
- Telmisartan 80 mg daily (n=8,542)
- Combination of telmisartan and ramipril (n=8,502)

**1° endpoint:** After a median follow-up of 56 mo, no difference between ramipril vs. telmisartan or combination therapy vs. ramipril in the 1° composite outcome of death from CV causes, MI, stroke, or hospitalization for HF RR: 1.01 (95% CI: 0.94–1.09) and RR: 0.99 (95% CI: 0.92–1.07), respectively.

**Safety endpoint:** Combination therapy was associated with greater risk of hyperkalemia than ramipril monotherapy (480 pts vs. 283 pts; p<0.001) and combination therapy vs. ramipril monotherapy RR: 1.54, p<0.001; and combination therapy vs. ramipril monotherapy RR: 2.75, p<0.001.

### ONTARGET Investigators, et al., 2008 (126) 18378520

**Aim:** Evaluate whether use of an ARB was noninferior to ACEI, and whether the combination was superior to ACE alone in the prevention of vascular events in pts with CVD or DM but not HF.

**Study type:** Multi-center, double-blind, RCT

**Size:** 25,620

**Inclusion criteria:**
- ≥55 y
- Coronary, peripheral, or cerebrovascular disease or DM with end-organ damage

**Exclusion criteria:**
- Inability to discontinue ACEI or ARB
- Known hypersensitivity or intolerance to ACEI or ARB
- Selected CVDs (congestive HF, hemodynamically significant valvular or outflow tract obstruction, constrictive pericarditis, complex congenital heart disease, syncopal episodes of unknown etiology <3 mo, planned cardiac surgery or PTCA <3 mo, uncontrolled HTN on treatment [e.g., BP >160/100 mm Hg], heart transplant recipient,

**Intervention:**
- Telmisartan 80 mg daily (n=8,542)
- Combination of telmisartan and ramipril (n=8,502)

### Summary:
- These analyses provided compelling evidence for the CV benefits of reduction in BP in pts with stage 1–3 CKD. The proportional reductions in risk of major CV events were similar in pts with and without evidence of CKD, however those with CKD stood to gain larger absolute benefits because their baseline risk was much higher.
- BP-lowering is an effective strategy for preventing CV events among pts with moderately reduced eGFR. There is little evidence from these overviews to support the preferential choice of particular drug classes for the prevention of CV events in CKD.
stroke due to subarachnoid hemorrhage)
- Other conditions (significant renal artery disease, hepatic dysfunction, uncorrected volume or sodium depletion, 1° hyperaldosteronism, hereditary fructose intolerance, other major noncardiac illness or expected to reduce life expectancy or significant disability interfere with study participation, simultaneously taking another experimental drug, unable to provide written informed consent).

| **VALIANT** White HD, et al., 2005 (182) | **Aim:** Evaluate whether use of an ARB or the combination of an ACEI and an ARB was superior to a proven effective dose of an ACEI after AMI in pts with HF and/or LVEF <40%.

**Study type:** Multi-center, double-blind, RCT

**Size:** 14,703 |
| **Inclusion criteria:**
- ≥18 y
- Between 12 h and 10 d after AMI
- Clinical or radiological signs of HF and/or evidence of depressed LV systolic function with EF<40% or reduced echo wall motion index

**Exclusion criteria:**
- Cardiogenic shock
- Serum creatinine >2.5 mg/dL
- Known hypersensitivity or intolerance to ACEI or ARB
- SBP<100 mm Hg
- Known or suspected bilateral renal artery stenosis
- Stroke or TIA within previous 3 mo
- Refractory ventricular arrhythmia
- Refractory angina
- Right ventricular MI
- Mitral stenosis, mitral regurgitation, aortic stenosis, aortic regurgitation of hemodynamic significance
- Obstructive cardiomyopathy
- Previous major organ transplant |
| **Intervention:** Valsartan 160 mg bid

**Comparator:**
- Captopril 50 mg tid
- Combination of captopril 50 mg tid and valsartan 160 mg bid
- Analyzed by prespecified age groups of
  - <65 (n=6,988)
  - 65 to 74 (n=4,555)
  - 75 to 84 (n=2,777)
  - ≥85 y (n=383)

**1° endpoint:** All-cause mortality

**2° endpoint:**
- Composite of CV mortality or emergency treatment or hospitalization for new or worsening HF, reinfarction, stroke, and resuscitated cardiac arrest
  - On 3-y multivariable analysis, each 10-y increase was associated with HR: 1.49 (95% CI: 1.43–1.56), p<0.0001 for mortality and OR: 1.38 (95% CI: 1.31–1.46; p<0.0001) for readmission with HF.
  - Similar but slightly smaller trend for composite endpoint, higher mainly in the oldest group.
  - Valsartan was at least as effective as captopril in reducing mortality and other adverse outcomes in all age groups and combination therapy with both agents added no incremental benefit.
  - Combination therapy increased the incidence of adverse effects leading to discontinuation in all age groups

**Safety endpoint:**
- Adverse events associated with captopril and valsartan were more common in the elderly and in pts receiving combination therapy.
- Renal dysfunction was more common with older age and combination therapy.
### Conditions likely to lead to poor adherence

- **SPRINT Senior Williamson JD, et al., 2016 (190) 27195814**

**Aim:** Intensive SBP goal <120 mm Hg) vs. standard (SBP goal <140)

**Study type:** RCT

**Size:** 2,636; 30% met criteria for being classified as ambulatory frail

**Mean follow-up:** 3.1 y

**Inclusion criteria:** Men and women age 75+; mean age 79.8 y; 38% women; 17% black, 74% Caucasian

**Exclusion criteria:** Nursing home residents; prevalent DM, stroke, Class III/IV HF, dementia

**Intervention:** Medications and dietary advice to achieve SBP of <120 mm Hg

**Comparator:** Medications and dietary advice to achieve SBP of <140 mm Hg

**Achieved SBP:** Intensive= 123.4 mm Hg Standard= 134.8 mm Hg

**1° endpoint:** Composite CVD outcome (AMI, non-MI ACS, Stroke, HF, CVD death.

**Results:**
- 102 events in the intensive treatment group vs. 148 events in the standard treatment group; HR: 0.66; 95% CI: 0.51–0.85 and all-cause mortality (73 deaths vs. 107 deaths, respectively; HR: 0.67; 95% CI: 0.49–0.91. No difference in falls, orthostatic hypotension, or overall SAEs.

**NNT for 1° outcome=27 and NNT for all-cause mortality=41**

**Limitations:** Does not apply to nursing home pts or those with dementia or advance

**Conclusions:** Intensive SBP is safe and effective for lowering CVD events and total mortality in adults ≥75 y

| INTERACT2 Anderson CS, et al., 2013 (191) 23713578 | **Aim:** To assess whether rapid lowering of elevated BP would improve the outcome in pts with ICH. | **Inclusion criteria:** Pts with spontaneous ICH within the previous 6 h with elevated SBP | **Design:** Intensive treatment to lower BP (with a target systolic level of <140 mm Hg within 1 h) vs. guideline-recommended treatment (with a target SBP <180 mm Hg) among pts with SBP between 150 and 220 mm using agents of the physician’s choosing. | **1° outcome:** Death or major disability (score of 3 to 6 on the modified Rankin scale) at 90 d. | **Summary:**
- In pts with ICH, intensive lowering of BP did not result in a significant reduction in the rate of death or severe disability.
- However, there may be improved functional outcomes with intensive lowering of BP.
- INTERACT-2 is so far the largest (and only phase 3) RCT evaluating efficacy of intensive BP lowering.

**Pre-specified 2° outcome:** Ordinal analysis of the modified Rankin score.
### ATACH-1

**Aim:** To determine the feasibility and acute (i.e., within 72 h) safety of 3 levels of SBP reduction in subjects with supratentorial ICH treated within 6 h after symptom onset.

**Study type:** Phase I, dose-escalation, multicenter prospective study.

**Study size:** 60

**Inclusion criteria:** Pts with ICH with elevated SBP ≥170 mm Hg who presented to the ED within 6 h of symptom onset.

**Design:**
- IV nicardipine to reduce SBP to a target of:
  - #1: 170–200 mm Hg in the first cohort of pts
  - #2: 140–170 mm Hg in the 2nd cohort
  - #3: 110–140 mm Hg in the third cohort.
- Each subject was followed-up for 3 mo to preliminarily assess mortality and the clinical outcomes. A total of 18, 20, and 22 pts were enrolled in the respective 3 tiers of SBP treatment goals.

**1° outcome:** Treatment feasibility (achieving and maintaining the SBP goals for 18–24 h)

**2° outcomes:**
- #1: Neurologic deterioration within 24 h;
- #2: Serious adverse events within 72 h.

**Key findings:**
- Overall, 9 of 60 pts had treatment failures (all in the last tier). A total of 7 subjects with neurologic deterioration were observed: 1 (6%), 2 (10%), and 4 (18%) in tier 1, 2, and 3, respectively.
- Serious adverse events were observed in 11 subject (5%) in tier 2 and in 3 subjects (14%) in tier 3. However, the safety stopping rule was not activated in any of the tiers.
- 3 (17%), 2 (10%), and 5 (23%) subjects in tiers 1, 2, and 3, respectively, died within 3 mo.

**Summary:**
- Observed proportions of neurologic deterioration and serious adverse events were below the prespecified safety thresholds, and the 3-mo mortality rate was lower than expected in all SBP tiers.

### INTERACT-1

**Aim:** To assess the safety and efficiency of early intensive lowering of BP (target SBP)

**Inclusion criteria:** Pts with ICH

**Design:** Early intensive lowering of BP (target SBP)

**1° outcome:** Proportional change in hematoma volume at 24 h.

**Summary:** Early intensive BP-lowering treatment is clinically...
<table>
<thead>

| COSSACS Robinson TG, et al., 2010 20621562 | **Aim:** Assess the efficacy and safety of continuing or stopping pre-existing antihypertensive drugs in patients with acute stroke  
**Study type:** RCT  
**Size:** 763 | **Inclusion criteria:**  
Acute ischemic stroke (or ICH) within previous 48 h  
**Exclusion criteria:**  
• Impaired level of consciousness  
• Unable to swallow  
• Hypertensive emergency  
• BP >200/120 mm Hg  
• Premorbid disability  
• Intravenous alteplase | **Intervention:** Continue previous antihypertensive medication/s (n=379)  
**Comparator:** Stop previous antihypertensive medication/s (n=384) | **1° endpoint:** Death or major disability (mRS 3–6) at 14 d: RR: 0.86 (95% CI: 0.65–1.14; p=0.3)  
**Safety endpoint:** Adverse events, minor and serious: p>0.05 for all | **Relevant 2° endpoint**  
2-wk NIHSS: p=0.46 and 2-wk Barthel Index: p=0.30  
2-wk BP: significantly lower in the continue arm (mean difference of -13 mm Hg in SBP and -8 mm Hg in DBP) p<0.0001  
6-month mortality: p=0.98; 6-month disability p<0.05  
**Study limitations**  
• Trial was terminated early because of slow recruitment, and consequently it was underpowered  
• Treatment was not homogeneous (different drugs, no specific BP target)  
• No differences when analysis restricted to patients with ischemic stroke  
**Summary/conclusions**  
• Early reinitiation of antihypertensive medications was safe but ineffective to prevent death or dependency  
• Early reinitiation of antihypertensives was associated with better BP control at 2 wk |

<tr>
<th>Inclusion criteria:</th>
<th>Prospective RCTs of pts ≥18 y with acute ischemic or hemorrhagic stroke; intervention compared with placebo was initiated within 7 d of stroke onset; intervention aimed to lower BP or intervention achieved BP reduction; 1 or more functional outcomes reported, such as death or dependency.</th>
</tr>
</thead>
</table>

<table>
<thead>
<tr>
<th>1° outcomes:</th>
<th>Early BP lowering after acute stroke onset compared with placebo</th>
</tr>
</thead>
</table>
| **Key findings:** | • Early BP lowering after acute stroke onset associated with more death within 30 d compared with placebo RR: 1.34; 95% CI: 1.02–1.74; p=0.03.  
• Early BP lowering after acute stroke onset not associated with early neurological deterioration, early death within 7 d, long-term death, early and long-term dependency, early and long-term combination of death or dependency, long-term stroke recurrence, long-term MI and long-term CVE. |

| **Relevant 2° endpoint** | • Death or major disability (mRS 3–5) at 90 d: OR: 0.99 (95% CI: 0.86–1.15; p=0.93)  
• Lower blood pressure at 14 d (mean difference of -8.6 mm Hg in SBP and -3.9 mm Hg in DBP; p<0.001) and at 90 d (mean difference of -2.9 mm Hg in SBP and -1.4 mm Hg in DBP; p<0.001) in the active arm |

| **Study limitations** | Antihypertensive regimen was not standardized |

| **Summary/conclusions** | Early treatment of hypertension was safe but ineffective to prevent death or dependency  
Early initiation of antihypertensives was associated with better BP control at 2 wk |

**Summary:** Results do not support early BP lowering after acute stroke. Early BP lowering may be associated with greater risk of death within 30 d after acute stroke.
**Zhao R, et al., 2015 (196) 26061309**

**Aim:** To determine whether lowering BP during the acute phase of an ischemic stroke improves short- and long-term outcomes.

**Study type:** Systematic review and meta-analysis of RCTs.

**Study size:** 22 RCTs

**Inclusion criteria:** Pts with acute stroke (ischemic or hemorrhagic) treated with an antihypertensive agent or placebo.

**Groups:** Treatment groups were n=5,672 (range, 6–2,308), and in the control groups was 5,416 (range, 6–2033).

**Follow-up:** Ranged from 5 d–12 mo

- Early BP lowering after acute stroke onset compared with placebo

**1° outcomes:** Change in SBP and DBP after treatment and short- and long-term dependency and mortality rates.

**Key findings:**
- Treatment groups had a greater decrease in BP than control groups, and this effect was seen with different classes of antihypertensive drugs.
- Short-term and long-term dependency rates were similar between treatment and control groups (short-term dependency: pooled OR: 1.041; 95% CI: 0.936–1.159; p=0.457; long-term dependency: pooled OR: 1.013; 95% CI: 0.915–1.120; p=0.806).
- Short-term or long-term mortality was similar between the treatment and control groups (short-term mortality: pooled OR: 1.020 (95% CI: 0.749–1.388; p=0.902); long-term mortality: pooled OR: 1.039 (95% CI: 0.883–1.222; p=0.644).

**Summary:** Antihypertensive agents effectively reduce BP during the acute phase of an ischemic stroke, but seem to confer no benefit with regard to short- and long-term dependency and mortality.

**Ahmed N, et al., 2000 (197) 10835440**

**Aim:** To investigate outcome in INWEST subgroups with increasing levels of BP reduction.

**Inclusion criteria:** Pts with a diagnosis of ischemic stroke in the carotid artery territory within 24 h.

**Interventions:**
- Nimodipine as IV infusion of 1 mg/h for 5 d followed by oral dose of 120 mg daily for a total treatment period of 21 d (n=101)

**1° outcomes:** Neurological outcome per the Orgogozo scale and functional outcome per the Barthel scale at d 21

**Key findings:**
- Nimodipine treatment resulted in a significant reduction in BP from baseline vs. placebo during the first few d.

**Summary:** DBP, but not SBP, reduction was associated with neurological worsening after the IV high-dose nimodipine after acute stroke.
- For low-dose nimodipine, the results were inconclusive.
<table>
<thead>
<tr>
<th>Study type: Post-hoc analysis of RCT</th>
<th>Size: 265</th>
</tr>
</thead>
</table>

**Comparator:** Placebo (n=100)

- Nimodipine as IV infusion of 2 mg/h for 5 d followed by oral dose of 120 mg daily for a total treatment period of 21 d (n=94)
- A significant correlation between DBP reduction and worsening of the neurological score was found for the high-dose group (beta=0.49; p=0.048).
- Pts with a DBP reduction of ≥20% in the high-dose group had a significantly increased adjusted OR for death or dependency (n/N=25/26, OR: 10.16; 95% CI: 1.02–101.74) and death alone (n/N=9/26, OR: 4.336; 95% CI: 1.131–16.619) vs. all placebo pts (n/N=62/92 and 14/92, respectively). No correlation between SBP change and outcome.

**Study type:** Meta-analysis of RCTs of interventions that aimed to alter BP compared with control in pts with 1 wk of acute ischemic or hemorrhagic stroke.

**Inclusion criteria:** RCTs of interventions that aimed to alter BP compared with control in pts with 1 wk of acute ischemic or hemorrhagic stroke.

**1° outcome:** Functional outcome

**Key findings:**
- At 24 h after randomization #1: Oral ACEIs reduced SBP MD: -8 mm Hg (95% CI: -17–1) and DBP MD: -3 mm Hg (95% CI: -9–2), sublingual ACEIs reduced SBP MD: -12.00 mm Hg (95% CI: -26–2) and DBP MD: -2 (95% CI: -10–6).
- Oral angiotensin receptor antagonists reduced SBP MD: -1 mm Hg (95% CI: -3–2) and DBP MD: -1 mm Hg (95% CI: -3–1).
- Oral BBs reduced SBP MD: -14 mm Hg (95% CI: -27–-1) and DBP MD: -1 mm Hg (95% CI: -9–7), IV BBs reduced SBP MD: -5 mm Hg (95% CI: -18–8) and DBP MD: -5 mm Hg (95% CI: -13–3).
- Oral CCBs reduced SBP MD: -13 mm Hg (95% CI: -43–17) and DBP MD: -6 mm Hg (95% CI: -14–2), IV CCBs reduced SBP MD: -32 mm Hg (95% CI: -65–1) and DBP MD: -13 (95% CI: -31–6).
- Nitric oxide donors reduced SBP MD: -12 mm Hg (95% CI: -19–-5) and DBP MD: -3 (95% CI: -4–-2).

**Summary:**
- No current evidence showing that lowering BP during the acute phase of stroke improves functional outcome.
- It seems reasonable to withhold BP-lowering drugs until pts are medically and neurologically stable, after which drugs can then be reintroduced.
- CCBs, ACEI, angiotensin receptor antagonists, BBs and nitric oxide donors each lower BP in acute stroke while phenylephrine appears to increase BP.

Bath PM, et al., 2014 (198) 25353321

**Aim:** To assess the clinical effectiveness of altering BP in pts with acute stroke, and the effect of different vasoactive drugs on BP in acute stroke. Update of previously published Cochrane reviews (1997, 2001, and 2008).

© 2017 American College of Cardiology Foundation and American Heart Association, Inc.
### 2017 Hypertension Guideline Data Supplements

| **Size:** 26 trials involving 17,011 pts (8,497 pts were assigned active therapy and 8,514 pts received placebo/control). Not all trials contributed to each outcome. | **● Phenylephrine, nonsignificantly increased SBP MD: 21 mm Hg (95% CI: -13–55) and DBP MD: 1 mm Hg (95% CI: -15–16).**  
**● BP lowering did not reduce death or dependency either by drug class OR: 0.98 (95% CI: 0.92–1.05), stroke type OR: 0.98 (95% CI: 0.92–1.05) or time to treatment OR: 0.98 (95% CI: 0.92–1.05).**  
**● Treatment within 6 h of stroke appeared effective in reducing death or dependency OR: 0.86 (95% CI: 0.76–0.99) but not death OR: 0.70 (95% CI: 0.38–1.26) by trial end.**  
**● While death or dependency did not differ between pts who continued pre-stroke antihypertensive treatment vs. those who stopped it temporarily (worse outcome with continuing treatment OR: 1.06; 95% CI: 0.91–1.24), disability scores at the end of the trial were worse in pts randomized to continue treatment (Barthel Index MD: -3.2 (95% CI: -5.8– -0.6).** |

| **SITS-ISTR** Ahmed N, et al., 2009 (199)  
19461022 | **Aim:** To determine the association of BP and antihypertensive therapy with clinical outcomes after thrombolysis for acute ischemic stroke  
**Study type:** Retrospective analysis of prospectively maintained thrombolysis registry. | **Inclusion criteria:**  
● Pts with acute ischemic stroke treated with IV rtPA  
● BP values were recorded at baseline, 2 h, and 24 h after thrombolysis.  
**Categories:** By history of HTN and antihypertensive therapy within 7 d after thrombolysis:  
● Group 1, HTN treated with antihypertensives (n=5,612)  
**1st outcomes:** Symptomatic (National Institutes of Health Stroke Scale score deterioration ≥4) ICH Type 2, mortality, and independence at (modified Rankin Score 0 to 2) 3 mo.  
**Key findings:**  
● High SBP 2–24 h after thrombolysis as a continuous variable was associated with worse outcome (p=0.001) and as a categorical variable had a linear association with symptomatic hemorrhage and a U-shaped association with mortality and independence with SBP 141–150 mm Hg associated with most favorable outcomes.  
● No difference in symptomatic hemorrhage OR: 1.09 (95% CI: 0.83–1.51; p=0.58) and independence OR: 1.03 (95% CI: 0.93–1.10; p=0.80) but lower mortality OR: 0.82 (95%)  
**Summary:**  
● Strong association of high SBP after thrombolysis with poor outcome.  
● Higher BPs during the initial 24 h were associated with greater risk of ICH in a linear fashion.  
● U-shaped relation found between BP during initial 24 h and death or dependency at 3 mo, with best outcomes associated with SBP of 141–150 mm Hg. |
### ACCESS

**Schrader J, et al., 2003 (200)**

**Aim:** To assess safety of modest BP reduction by candesartan in early treatment of stroke; and provide an estimate of the number of cases required to perform a larger phase III efficacy study.

**Study type:** Prospective, double-blind, RCT; multicenter phase II study.

**Size:** 342 pts

**Study size:**

- Group 2, HTN withholding antihypertensives (n=1,573)
- Group 3, without history of HTN treated with antihypertensives (n=995)
- Group 4, without history of HTN not treated with antihypertensives (n=2,632).

**Inclusion criteria:**
- Motor deficit, a cerebral CT scan excluding ICH, and necessity to treat HTN per prevailing recommendation

**Exclusion criteria:**
- >85 y, disorders in consciousness preventing acquisition of consent, occlusion or >70% stenosis of the internal carotid artery, malignant HTN, manifest cardiac failure, high-grade aortic or mitral stenosis, UA pectoris, or contraindications against candesartan.

**Design:**
- 4 mg candesartan daily or placebo on d 1. On d 2, dosage was increased to 8 or 16 mg candesartan or placebo if BP >60 mm Hg SPB or 100 mm Hg DBP. Treatment was targeted to a 10%–15% BP reduction within 24 h.

**1º outcome:**
- Trial was stopped prematurely when 342 pts (339 valid) had been randomized because of an imbalance in endpoints.

**Key findings:**
- Cumulative 12 mo mortality and the number of vascular events differed significantly in favor of the candesartan cilexetil group (OR: 0.475; 95% CI: 0.252–0.895).

**Summary:**
- Early antihypertensive therapy with candesartan might be a safe therapeutic option in acute stroke, but study sample size very small.

### SCAST

**Sandset EC, et al., 2011 (201)**

**Aim:** To examine whether careful BP-lowering treatment with the candesartan is

**Inclusion criteria:**
- Pts >18 y with acute stroke (ischemic or hemorrhagic) and SBP of ≥140 mm Hg were randomized to candesartan (n=1,017) or placebo (1,012) (1:1) for 7 d, with doses

**Design:**
- Pts randomized to candesartan (n=1,017) or placebo (1,012) (1:1) for 7 d, with doses

**1º effect variables:**
- Composite of vascular death, MI, or stroke during the first 6 mo; and functional outcome at 6 mo, as measured by the modified Rankin Scale.

**Relevant 2º endpoint:**
- Similar effects for all prespecified 2º endpoints.
- During follow-up, 9 (1%) pts on candesartan and 5 (<1%) on
### CATIS

**He J, et al., 2014 (202) 24240777**

**Aim:** To evaluate whether immediate BP reduction in pts with acute ischemic stroke would reduce death and major disability at 14 d or hospital discharge.

**Study type:** Single-blind, blinded end-points RCT.

**Study size:** 4,071 pts

**Inclusion criteria:** Pts with nonthrombolysed ischemic stroke within 48 h of onset and elevated SBP

**Design:** Pts (n=2,038) randomized to antihypertensive treatment (aimed at lowering SBP by 10% to 25% within first 24 h, achieving BP <140/90 mm Hg within 7 d, and maintaining this level during hospitalization) vs. to discontinue all antihypertensive medications (control) during hospitalization (n=2,033).

**1° outcome:** Combination of death and major disability (modified Rankin Scale score ≥3) at 14 d or hospital discharge.

**Key findings:**
- Mean SBP was reduced from 166.7 mm Hg to 144.7 mm Hg (-12.7%) within 24 h in the antihypertensive treatment group and from 165.6 mm Hg to 152.9 mm Hg (-7.2%) in the control group within 24 h after randomization (difference, -5.5% (95% CI: -4.9– -6.1%); absolute difference, -9.1 mm Hg (95% CI: -10.2– -8.1), p<0.001).
- 1° outcome did not differ between treatment groups (OR: 1.00; 95% CI: 0.88–1.14; p=0.98) at 14 d or hospital discharge.
- BP at 14 d and 90 d: significantly lower in the active arm (mean difference of -2.9 mm Hg in systolic BP and -1.4 mm Hg in diastolic BP)

**Relevant 2° endpoint:** Death and major disability at 3-mo posttreatment follow-up did not differ between treatment groups (500 events [antihypertensive treatment] vs. 502 events [control]; OR: 0.99; 95% CI: 0.86–1.15; p=0.93).

**Summary:** Among pts with acute ischemic stroke, BP reduction with antihypertensive medications, vs. absence of hypertensive medication, did not reduce the likelihood of death and major disability at 14 d or hospital discharge.

- Early initiation of antihypertensives was associated with better BP control at 2 wk

<td><strong>COSSACS</strong>&lt;br&gt;Robinson TG, et al., 2010 (203) 20621562</td>
<td>To assess the efficacy and safety of continuing or stopping pre-existing antihypertensive drugs in pts who recently had a stroke.</td>
<td>Pts &gt;18 y taking antihypertensive drugs enrolled within 48 h of stroke and last dose of antihypertensive drug.</td>
<td>Continue (n=379) or stop (n=384) pre-existing antihypertensive drugs for 2 wk.</td>
<td>Death or dependency at 2 wk.</td>
<td>● 72 of 379 pts in the continue group and 82 of 384 pts in the stop group reached the 1° endpoint RR: 0.86; 95% CI: 0.65–1.14; p=0.3. ● Difference in SBP at 2 wk between the continue group and the stop group was 13 mm Hg (95% CI: 10–17) and the difference in DBP was 8 mm Hg (6–10; difference between groups; p&lt;0.0001). ● No substantial differences were observed between groups in rates of serious adverse events, 6-mo mortality, or major CV events.</td>
<td>● Continuation of antihypertensive drugs did not reduce 2-wk death or dependency, CV event rate, or mortality at 6 mo ● Early reinitiation of antihypertensives was associated with better BP control at 2 wk ● Lower BP levels in those who continued antihypertensive treatment after acute mild stroke were not associated with an increase in adverse events. ● Of note, COSSACS was likely underpowered due to early termination of the trial.</td>
</tr>
<tr>
<td><strong>CHIPS</strong>&lt;br&gt;Potter JF, et al., 2009 (204) 19058760</td>
<td>To assess feasibility, safety, and effects of 2 regimens for lowering BP in pts who with acute stroke.</td>
<td>Pts with cerebral infarction or cerebral hemorrhage who were hypertensive SBP &gt;160 mm Hg</td>
<td>Within 36 h of symptom onset: #1: Oral labetalol, lisinopril vs. placebo if they were nondysphagic; #2: IV labetalol, sublingual lisinopril, or placebo if they had dysphagia. ● Labetalol (n=58), lisinopril (n=58), or placebo (n=63). ● Doses were titrated up if target BP was not reached.</td>
<td>Death or dependency at 2 wk.</td>
<td>● 1° outcome occurred in 61% (69) of the active vs. 59% (35) of the placebo group (RR: 1.03; 95% CI: 0.80–1.33; p=0.82) ● No evidence of early neurological deterioration with active treatment (RR: 1.22; 95% CI: 0.33–4.54; p=0.76) despite greater drop in SBP within the first 24 h in this group vs. placebo (21 [17–25] mm Hg vs. 11 [5–17] mm Hg; p=0.004). ● No rise in serious adverse events with active treatment (RR: 0.91; 95% CI: 0.69–1.12; p=0.50) but 3-mo mortality was halved (9.7% vs. 20.3%; HR: 0.40; 95% CI: 0.2–1.0; p=0.05).</td>
<td>● Labetalol and lisinopril are effective antihypertensive drugs in acute stroke that do not raise risk of serious adverse events. ● Early lowering of BP with lisinopril and labetalol after acute stroke may be a promising approach to lower mortality and disability. ● However, pilot nature and very small sample size limit generalizability.</td>

| ATACH-1 2010 (192) 19770736 | Drugs to lower their BP.  
**Study type:** Multicenter, randomized partial-factorial trial  
**Study size:** 4,011 pts or hemorrhagic stroke and raised SBP (140–220 mm Hg) per d), started within 48 h of stroke onset vs. No glyceryl trinitrate (control group).  
**Study size:** 4,011 pts  
**Key findings:**  
- Mean BP was 167 (SD: 19) mm Hg/90 (13) mm Hg at baseline (median 26 h (16–37) after stroke onset), and was significantly reduced on d 1 in 2,000 pts allocated to glyceryl trinitrate vs. 2,011 controls (difference -7.0 (95% CI: -8.5--5.6) mm Hg/-3.5 [-4.4--2.6] mm Hg; both p<0.0001), and on d 7 in 1,053 pts allocated to continue antihypertensive drugs compared with 1,044 pts randomized to stop them (difference: -9·5 (95% CI: -11.8--7.2) mm Hg/-5.0 [-6.4--3.7] mm Hg; both p<0.0001).  
- D-90 functional outcome did not differ in either treatment comparison-glyceryl trinitrate vs. no glyceryl trinitrate (OR: 1.01; 95% CI 0.91–1.13; p=0.83), and with continue vs. stop antihypertensive drugs (OR: 1.05; 95% CI: 0.90–1.22; p=0.55).  
- Continuing prestroke antihypertensive drugs in acute stroke pts in the first few d did not confer benefit.

### ATACH-1 2010 (192) 19770736

| Aim: To determine the feasibility and acute (i.e., within 72 h) safety of 3 levels of SBP reduction in subjects with supratentorial ICH treated within 6 h after symptom onset.  
**Study type:** Phase I, dose-escalation, multicenter prospective study.  
**Study size:** 60 pts | **Inclusion criteria:** Pts with ICH with elevated SBP ≥170 mm Hg who presented to the ED within 6 h of symptom onset.  
**Design:**  
- IV nicardipine to reduce SBP to a target of:  
  #1: 170–200 mm Hg in the first cohort of pts  
  #2: 140–170 mm Hg in the 2nd cohort  
  #3: 110–140 mm Hg in the third cohort.  
- Each subject was followed-up for 3 mo to preliminarily assess mortality and the clinical outcomes. A total of 18, 20, and 22 pts were enrolled in the respective 3 tiers of SBP treatment goals.  
**1º outcome:** Treatment feasibility (achieving and maintaining the SBP goals for 18–24 h)  
**2º outcomes:**  
#1: Neurologic deterioration within 24 h;  
#2: Serious adverse events within 72 h.  
**Key findings:**  
- Overall, 9 of 60 pts had treatment failures (all in the last tier). A total of 7 subjects with neurologic deterioration were observed: 1 (6%), 2 (10%), and 4 (18%) in tier 1, 2, and 3, respectively.  
- Serious adverse events were observed in1 subject (5%) in tier 2 and in 3 subjects (14%) in tier 3. However, the safety stopping rule was not activated in any of the tiers.  
- 3 (17%), 2 (10%), and 5 (23%) subjects in tiers1, 2, and 3, respectively, died within 3 mo  
**Summary:**  
- Observed proportions of neurologic deterioration and serious adverse events were below the prespecified safety thresholds, and the 3-mo mortality rate was lower than expected in all SBP tiers.  
- Results formed the basis of an ongoing larger randomized trial (ATACH-2) addressing the efficacy of SBP reduction in pts with ICH.

© 2017 American College of Cardiology Foundation and American Heart Association, Inc.
### INTERACT-1

**Aim:** To assess the safety and efficiency of this treatment, as a run-in phase to a larger trial.

**Study type:** Randomized pilot trial

**Study size:** 404

**Inclusion criteria:** Pts with acute spontaneous ICH diagnosed by CT within 6 h of onset, elevated SBP (150–220 mm Hg), and no definite indication or contraindication to treatment

**Design:** Early intensive lowering of BP (target SBP 140 mm Hg; n=203) vs. standard guideline-based management of BP (target SBP 180 mm Hg; n=201).

**1° outcome:** Proportional change in hematoma volume at 24 h.

**2° outcomes:** Measurements of hematoma volume.

**Safety and clinical outcomes:** Assessed for up to 90 d.

**Key findings:**
- Mean hematoma volumes were smaller in the guideline group (12.7 mL, SD 11.6) than in the intensive group (14.2 mL, SD 14.5).
- From randomization to 1 h, mean SBP was 153 mm Hg in the intensive group and 167 mm Hg in the guideline group (difference 13.3 mm Hg (95% CI: 8.9–17.6) mm Hg; p<0.0001); from 1 h to 24 h, BP was 146 mm Hg in the intensive group and 157 mm Hg in the guideline group (10.8 mm Hg; 95% CI: 7.7–13.9 mm Hg; p<0.0001).
- Mean proportional hematoma growth was 36.3% in the guideline group and 13.7% in the intensive group (difference 22.6%; 95% CI: 0.6%–44.5%; p=0.04) at 24 h.
- After adjustment for initial hematoma volume and time from onset to CT, median hematoma growth differed between the groups with p=0.06; the absolute difference in volume between groups was 1.7 mL (95% CI: -0.5–3.9; p=0.13). RR of hematoma growth ≥33% or ≥12.5 mL was 36% lower (95% CI: 0%–59%; p=0.05) in the intensive group than in the guideline group. Adjusted RR: 8% (95% CI: -1.0%–17%; p=0.05).
- Intensive BP-lowering treatment did not alter the risks of adverse events or 2° clinical outcomes at 90 d.

**Summary:** Early intensive BP-lowering treatment is clinically feasible, well tolerated, and appears to reduce hematoma growth in ICH.

### Hack W, et al., 2008 (206)

**Aim:** To assess the efficacy and effectiveness of IV alteplase administered between 3 h and 4.5 h of symptom onset.

**Inclusion criteria:** Pts 18–80 y, who had acute ischemic stroke with NIH Stroke Scale score of 0–18 within 6 h.

**Design:** 1° outcome: Disability at 90 d, dichotomized as a favorable outcome (a score of 0 or 1 on the NIH Stroke Scale).

**Summary:** Compared with placebo, IV alteplase administered between 3 h and 4.5 h of symptom onset reduced the risk of 1° disability at 90 d by 32% (95% CI: 12%–47%; p=0.005) and the risk of 2° severe disability (NIH Stroke Scale score 5–21) by 18% (95% CI: 2%–33%; p=0.03).
| NINDS rt-PA Stroke Study Group, 1995 (207) 7477192 | Aim: To assess the difference in clinical efficacy between IV t-PA and placebo among pts with an acute ischemic stroke | Inclusion criteria: Pts with an ischemic stroke with a clearly defined time of onset (<3 h), a deficit measurable on the NIH stroke scale, and a base-line CT scan of the brain that showed no evidence of ICH. | Design: RCT with acute ischemic stroke pts randomized to t-PA vs. placebo | 1° outcome: Clinical outcome at 3 mo, according to scores on the Barthel index, modified Rankin scale, Glasgow outcome scale, and NIH stroke scale: | Key findings: | Summary: Despite an increased incidence of symptomatic ICH, treatment with IV t-PA within 3 h of the onset of ischemic stroke improved clinical outcome at 3 mo |
| 18815396 | safety of alteplase administered between 3 and 4.5 h after the onset of a stroke. | received a clinical diagnosis of acute ischemic stroke, and were able to receive the study drug within 3–4 h after the onset of symptoms. | Exclusion criteria: | ● Eligible pts were randomly assigned 1:1 to receive 0.9 mg of alteplase per kg, administered IV (with an upper limit of 90 mg), or placebo. | 418 pts were assigned to receive alteplase and 403 pts were assigned to receive placebo | Key findings: |● More pts had a favorable outcome with alteplase than with placebo (52.4% vs. 45.2%; OR: 1.34; 95% CI: 1.02–1.76; p=0.04. |● Incidence of ICH was higher with alteplase than with placebo (for any ICH, 27.0% vs. 17.6%; p=0.001; for symptomatic intracranial hemorrhage, 2.4% vs. 0.2%; p=0.008). |● Mortality did not differ significantly between the alteplase and placebo groups (7.7% and 8.4%, respectively; p=0.68). |● No significant difference in the rate of other serious adverse events. |● As compared with pts given placebo, pts treated with t-PA were at least 30% more likely to have minimal or no disability at 3 mo on the assessment scales. |● Symptomatic ICH within 36 h after the onset of stroke occurred in 6.4% of pts given placebo and 4.5 h after the onset of symptoms significantly improved clinical outcomes in pts with acute ischemic stroke; alteplase was more frequently associated with symptomatic ICH. |
### Study size: 624 pts

SBP >185 mm Hg or DBP >110 mm Hg

- **t-PA but only 0.6% of pts given placebo (p<0.001).**
  - Mortality at 3 mo was 17% in the t-PA group and 2% in the placebo group (p=0.30).

<td><strong>Post-stroke Antihypertensive Treatment Study (PATS) 1995 (208)</strong> 8575241</td>
<td><strong>Aim:</strong> To assess whether lowering BP prevents the recurrence of stroke in Chinese pts with history of cerebrovascular disease</td>
<td><strong>Inclusion criteria:</strong> Pts with history of stroke or TIA</td>
<td><strong>Exclusion criteria:</strong> N/A</td>
<td><strong>Intervention:</strong> Indapamide 2.5 mg daily (n=2,840 pts)</td>
<td><strong>1° outcome:</strong> Recurrence of fatal or nonfatal stroke. <strong>Key findings:</strong> Average SBP/DBP at randomization was 153.8/92.8 mm Hg. At median follow-up (2 y), BP was 6.8/3.3 mm Hg lower in pts on active treatment. 143 pts on indapamide vs. 219 pts on placebo had recurrent strokes (HR: 0.69; 95% CI: 0.54–0.89; p&lt;0.001).</td>
<td><strong>2° outcome:</strong> Major fatal and nonfatal CV events. In addition, 199 pts on indapamide and 258 pts on placebo had a CV event (HR: 0.75; 95% CI: 0.89–0.62; p=0.002). 2.825 pts received a placebo and 2,840 pts received. <strong>Summary:</strong> For pts with a history of stroke or TIA, BP reduction of 5/2 mm Hg with 2.5 mg of indapamide lowered the first incidence of fatal and nonfatal stroke by 29%, with 3-y absolute benefit of 29 events per 1,000 pts.</td>
</tr>
<tr>
<td><strong>PROGRESS 2001 (209)</strong> 11589932</td>
<td><strong>Aim:</strong> To determine effects of a BP-lowering regimen in hypertensive and nonhypertensive pts with a history of stroke or TIA.</td>
<td><strong>Inclusion criteria:</strong> Pts with history of stroke (evidence of an acute disturbance of focal neurological function with symptoms lasting more than 24 h and</td>
<td></td>
<td><strong>Intervention:</strong> Active treatment comprised a flexible regimen based on the ACEI perindopril (4 mg daily), with addition of diuretic indapamide at discretion of treating physicians (n=3,051)</td>
<td><strong>1° outcome:</strong> Total stroke (fatal or nonfatal) <strong>Key findings:</strong> Over 4 y of follow-up, active treatment reduced BP by 9/4 mm Hg. 307 (10%) pts assigned active treatment suffered a stroke, vs. 420 (14%) assigned placebo (RR reduction: 28% [95% CI: 17, 38], p&lt;0.0001). Combination therapy with perindopril plus indapamide reduced BP by 12/5 mm Hg and stroke risk by 43% (95% CI: 30–54%). Single-drug therapy reduced BP. <strong>Relevant 2° endpoint:</strong> Active treatment also reduced the risk of total major vascular events (26% [16–34]). There were similar reductions in the risk of stroke in hypertensive and nonhypertensive subgroups (all p&lt;0.01). <strong>Summary:</strong> This BP-lowering regimen reduced the risk of stroke among both hypertensive and nonhypertensive pts with a history of stroke or TIA. Combination therapy with perindopril and indapamide produced larger BP.</td>
<td></td>
</tr>
<tr>
<td>MOSES</td>
<td>Aim: To assess among hypertensive stroke pts, whether for the same level of BP control, eprosartan would be more effective than nitrendipine in reducing cerebrovascular and CV morbidity and mortality.</td>
<td>Inclusion criteria: High-risk hypertensives with cerebral event during the last 24 mo (proven by cerebral CT scan or nuclear magnetic resonance)</td>
<td>Intervention: Eprosartan 600 mg (n=681)</td>
<td>1° endpoint: Composite of total mortality and all CV and cerebrovascular events, including all recurrent events.</td>
<td>Relevant 2° endpoint: CV events were: 77 eprosartan and 101 nitrendipine (IDR: 0.75; 95% CI: 0.55–1.02; p=0.06); cerebrovascular events: 102 eprosartan and 134 nitrendipine (IDR: 0.75; 95% CI: 0.58–0.97; p=0.03).</td>
<td>Summary: ● The combined 1° endpoint was significantly lower in the eprosartan group. ● However, it was a reduction in TIAs that accounted for most of the benefit in cerebrovascular events, with no significant difference in ischemic strokes. ● Also a more traditional analysis of time to first cerebrovascular event did not show a benefit of eprosartan.</td>

</tr>
</tbody>
</table>
with recent lacunar stroke.

**Study type:** Randomized open-label trial

**Size:** 3,020 pts

<table>
<thead>
<tr>
<th>Comparator: SBP target of &lt;130 mm Hg (n=1,501)</th>
</tr>
</thead>
<tbody>
<tr>
<td>● After 1 y, mean SBP was 138 mm Hg (95% CI: 137–139) in the higher-target group and 127 mm Hg (95% CI: 126–128) in the lower-target group.</td>
</tr>
<tr>
<td>● Recurrent stroke was observed in 152 pts assigned to higher-target group (2.8% per y) vs. 125 assigned to the lower-target group (2.3% per y; HR: 0.81; 95% CI: 0.64–1.03).</td>
</tr>
<tr>
<td>● Hemorrhagic stroke occurred in 16 pts assigned to the higher-target group (0.29% per y) vs. 6 assigned to the lower-target group (0.11% per y; HR: 0.37 (95% CI: 0.15–0.95). Serious complications of hypotension were observed in 15 pts assigned to the higher-target group (0.26% per y) and 23 assigned to the lower-target group (0.40% per y; HR: 1.53; 95% CI: 0.80–2.93).</td>
</tr>
</tbody>
</table>

**Summary:** Use of a SBP target of less than 130 mm Hg was not significantly better than a target of 130–149 mm Hg for preventing any recurrent stroke. However, the lower target appeared to confer benefit for prevention of hemorrhagic stroke.

### Aim: To examine role of BP reduction using antihypertensive agents to prevent recurrent stroke.

**Study type:** Systematic review and meta-analysis  
**Size:** 10 RCTs

**Inclusion criteria:** Pts with a history of ischemic stroke, TIA, or ICH  
Followed up 2 to 5 y.

**Exclusion criteria:** N/A

1° **outcome:** Recurrent stroke

**Key findings:** Antihypertensive drugs associated with significant reduction in recurrent strokes (RR: 0.78; 95% CI: 0.68–0.90).

Impact of antihypertensive treatment after ischemic stroke was similar in a restricted group of subjects with HTN and when all subjects, including those with and without HTN, were included.

Pooled OR: 0.63 (95% CI: 0.54–0.73; p<0.0001) for trials involving diuretics as a component of therapy and 0.93 (95% CI: 0.87–1.01; p=0.086) for trials in which treatment included renin system inhibitors (p<0.0001 for heterogeneity).

**Summary:** Achieving an SBP $<$130 mm Hg appears to provide additional stroke protection only among pts with risk factors but no established CVD.

### Lee M, et al., 2012 (216)  
21796663

**Aim:** To compare impact of achieving tight vs. usual SBP control on stroke prevention  
**Study size:** 11 studies with 42,572 pts and 794 stroke events.

**Inclusion criteria:**  
(1) Achieved SBP $<$130 mm Hg in an active treatment group and SBP 130 to 39 mm Hg in a comparator group by trial;  
(2) trial duration at least 6 mo;  
(3) total pts and number of stroke events reported separately for active treatment and comparator groups.

**Exclusion criteria:**  
(1) Nonrandomized trials;  
(2) trials in which either the

1° **outcome:** Association of future stroke risk and achieved level of different SBP (intensive vs. usual)

**Key findings:**  
- Final SBPs, weighted for trial size, were a mean of 126.5 mm Hg in the intensive treatment arms and 132.6 mm Hg in the conventional arms (mean SBP reduction, 6.1 mm Hg).
- In subgroup analyses, those with established (symptomatic) CVD at entry did not experience stroke risk reduction with tight control (0.92; 95% CI: 0.83–1.03).

**Summary:** In conclusion, BP lowering by indapamide treatment reduced the recurrence of stroke and the incidence of CV events in Chinese pts with cerebrovascular disease. Whether prevention of stroke recurrence depends on drug class, degree of BP lowering or both requires further investigation.
| **Lee M, et al., 2012 (217) 22052520** | **Aim:** To evaluate whether use of ACEIs or ARB reduces future vascular events in persons with prior stroke.  
**Size:** 8 RCTs with 29,667 pts  
**Inclusion criteria:** (1) RCT design; (2) pts had a history of stroke or TIA; (3) active treatment consisted of ACEIs or ARBs; (4) follow-up duration at least 6 mo; (5) total pts and number of future major vascular events and/or recurrent stroke were reported separately for active treatment and comparator groups.  
**Exclusion criteria:** (1) mandatory ACEI or ARB use in control groups; (2) study purpose was to examine efficacy of ACEIs or ARBs in pts with acute stroke.  
**1st outcome:** Major vascular event (nonfatal stroke, nonfatal MI, or death from CV causes) or stroke (ischemic or hemorrhagic)  
**Key findings:** Use of ACEIs or ARBs in persons with prior stroke was associated with lower risks of future major vascular events RR: 0.91 (95% CI: 0.87–0.97; p=0.001); NNT=71 and recurrent stroke RR: 0.93 (95% CI: 0.86–0.99; p=0.03); NNT=143.  
**Summary:** Treatment with an ACEI or ARB has a clear but rather modest effect on reducing vascular risk in persons with prior stroke. |  |  |
| **Arima H, et al., 2006 (218) 16685221** | **Aims:**  
#1: To investigate the effects of randomized treatment on recurrent stroke by baseline BP levels  
#2: To investigate association  
**Inclusion criteria:** Pts with history of cerebrovascular event (stroke or TIA) within the previous 5 y  
**Groups:** Defined by baseline BP of <120, 120–139, 140–159, and 160 mm Hg or greater  
**1st outcome:** Total stroke (fatal or nonfatal)  
**Key findings:**  
- Smaller BP differences between active vs. placebo groups (p<0.0001) and corresponding lesser risk reductions (p trend=0.05) with lower baseline BPs.  
**Summary:** These analyses provide no evidence of a J-curve relationship between BP level and stroke risk among pts with cerebrovascular disease. However, ischemic stroke, TIA, and hemorrhagic pts were all enrolled and within 5 y of the index event suggesting that these pts were generally neurologically stable and not acknowledging the...
between achieved follow-up BP levels and recurrent stroke risk.

**Study type:** Post-hoc analysis of PROGRESS trial.

**Size:** 6,105 pts

Follow-up SBP level was strong and continuous with no evidence of a J-curve in the range of achieved follow-up SBP from 112–168 mm Hg (p trend <0.0001 RR of study treatment on the discontinuation of randomized treatment increased progressively across the subgroups with lower baseline SBP levels at entry (p trend=0.04), but there was no corresponding difference in effects of randomized treatment on the risks of death or hospital admission (both p trend >0.2) or hypotension, renal dysfunction, electrolyte disturbance, hip fracture, or depression between pts with different levels of baseline BP at baseline (all p trend >0.1).

- Minor side-effects were progressively more common at lower BP levels (p homogeneity=0.04).

White CL, et al., 2015 (219)

**Aim:** To determine safety and tolerability of lowering BP in older adults with lacunar stroke

**Study type:** Post-hoc analysis of randomized trial

**Study Size:** 494 pts

**Inclusion criteria:** Pts with lacunar stroke ≥75 y

**1st outcome:** Rates of side effects related to lowering SBP

**2nd outcome:** Stroke recurrence and death from vascular causes

**Key findings:**
- Older pts achieved SBP levels similar to younger pts (mean SBP of 125 mm Hg in lower SBP target group and 137 mm Hg in higher target group)
- 3.5 y of follow-up 21% reported dizziness and 15% reported lightheadedness when standing; only significant difference between younger and older groups was unsteadiness when standing (23% vs. 32%, p<0.001). No difference in recurrent stroke by target SBP level among the older subjects (HR: 1.01; 95% CI: 0.59–1.73), but the differences in pathophysiologic mechanism between stroke types.
- First analysis showed that the effectiveness of antihypertensive treatment for 2nd stroke prevention diminished as baseline BP declined (relative RRs were 39%, 31%, 14%, and 0%, respectively, in the groups defined previously). This trend of decreasing effect was despite successful reduction of mean SBP in each active-treatment group compared with placebo (11.1, 9.2, 7.6, and 7.4 mm Hg reductions, respectively, in the groups defined previously). Also of note, 40% of pts with a baseline BP<140 mm Hg were taking antihypertensive therapy at baseline.

**Summary:** Pts ≥75 y with a recent lacunar stroke who achieved a lower SBP target (<130 mm Hg) were significantly more likely to report unsteadiness on standing than their younger counterparts. Lower SBP was not related to a decrease in recurrent stroke risk in elderly pts with lacunar stroke but there was a potential protective advantage from vascular death.
### Ovbiagele B, et al., 2011 (220)

**Aim:** To assess the association of maintaining low-normal vs. high-normal SBP levels with risk of recurrent stroke.

**Study type:** Post hoc analysis of a multicenter trial involving 20,330 pts (age ≥50 y) with recent noncardioembolic ischemic stroke followed up for 2.5 y

**Study Size:** 20,330 pts

**Inclusion criteria:** Pts 55 y or older with an ischemic stroke <90 d before randomization

**Categories:** Based on mean in-trial SBP value was very low-normal (<120 mm Hg), low-normal (120≤130 mm Hg), high-normal (130≤140 mm Hg), high (140≤150 mm Hg), and very high (>150 mm Hg).

- **1° outcome:** First recurrence of stroke of any type
- **2° outcome:** Composite of stroke, MI, or death from vascular causes

**Key findings:** Recurrent stroke rates were 8.0% (95% CI: 6.8%–9.2%) for the very low-normal SBP level group, 7.2% (95% CI: 6.4%–8.0%) for the low-normal SBP group, 6.8% (95% CI: 6.1%–7.4%) for the high-normal SBP group, and 14.1% (95% CI: 13.0%–15.2%) for the very high SBP group. Compared with pts in the high-normal SBP group, the risk of 1° outcome was higher for pts in the very low-normal SBP group AHR: 1.29 (95% CI: 1.07–1.56), in the high SBP group AHR: 1.24 (95% CI: 1.11–1.39), and in the very high SBP group AHR: 1.94 (95% CI: 1.74–2.16).

**Summary:** Among pts with recent noncardioembolic ischemic stroke, SBP levels during follow-up in the very low-normal (<120 mm Hg), high (140–≤150 mm Hg), or very high (≥150 mm Hg) range were associated with increased risk of recurrent stroke.

### Ovbiagele B, et al., 2013 (221)

**Aim:** To assess association of maintaining low-normal vs. high-normal SBP levels with risk of recurrent stroke.

**Study type:** Post hoc analysis of a multicenter trial involving 3,680 pts with recent noncardioembolic ischemic stroke followed up for 2 y

**Inclusion criteria:** Pts with an ischemic stroke <120 d before randomization

**Categories:** Based on mean in-trial SBP value was low-normal (<120 mm Hg), high-normal (120 to <140 mm Hg), or high (>140 mm Hg).

- **1° outcome:** First recurrence of stroke of any type

**Key findings:** Rate of recurrent stroke was 9.1% in the low-normal group, 6.7% in the high-normal group, and 10% in the high group. Over study period, compared with the high-normal SBP group, the risk of 1° outcome trended higher in the low-normal SBP group AHR: 1.29 (95% CI: 1.07–1.56), in the high SBP group AHR: 1.23 (95% CI: 1.07–1.41), and in the very high SBP group AHR: 1.92 (95% CI: 1.83–2.37).

**Summary:** Results support a possible pattern of increased risk of recurrent stroke in pts with low-normal SBP levels, especially within the first 6 mo after first stroke. However, this study likely was not sufficiently powered to detect more than a strong statistical trend underlying this relationship.
| Lin MP, et al., 2015 (222) 25765723 | **Aim:** To assess link between SBP and mortality after stroke.  
**Study type:** Analyses of nationally representative survey data (NHANES)  
**Study Size:** 455 pts | **Inclusion criteria:** Adults ≥20 y with self-reported stroke.  
**Categories:** Baseline SBP was as low to normal (<120 mm Hg), normal (120–140 mm Hg), and high (≥140 mm Hg).  
**1° outcomes:** All-cause and vascular mortality  
**Key findings:**  
2 y after assessment, the low to normal SBP group tended to have the highest cumulative all-cause mortality (11.5%), compared with mortality rates of 8.5% and 7.5% in the normal and high SBP groups, respectively. Similar patterns were seen with vascular mortality. After adjusting for covariates, compared with the high SBP group, the low to normal group had higher all-cause mortality AHR: 1.96 (95% CI: 1.13–3.39; p=0.017) and trended toward higher vascular mortality AHR: 2.08 (95% CI: 0.93–4.6; p=0.075). Compared with the normal BP group, the risk of all-cause and vascular mortality trended higher in low to normal BP group but did not achieve statistical significance.  
**Summary:** After stroke, compared with SBP in the high range, low to normal SBP may be associated with poorer mortality outcomes. Study limited by self-reported nature and retrospective design. |
| Kim J, et al., 2014 (223) 24509123 | **Aim:** To investigate the association between BP and vascular events up to 10 y after stroke.  
**Study type:** Analysis of population based study (North East Melbourne Stroke Incidence Study (NEMESIS))  
**Follow-up:** Annually by telephone at 6, 8, and 9 y and face-to-face interview at 7 and 10 y after stroke.  
**Inclusion criteria:** 5-y survivors of stroke  
**Categories:** Stratification by quartiles of SBP  
**1° outcomes:** Composite of all-cause death or nonfatal vascular event (stroke or AMI); and all-cause death alone.  
**Key findings:** In 5-y survivors of stroke, compared to a SBP of 131–141 mm Hg, SBP of 120 mm Hg or less was associated with a 61% greater risk of stroke, acute MI and death (HR: 1.61; 95% CI: 1.08–2.41; p=0.019). Compared to the reference category of SBP 131–141 mm Hg, there were no differences in outcome in the pts with SBP 121–130 mm Hg (p=0.491) or 142–210 mm Hg (p=0.313). Findings were not modified after adjusting for antihypertensive drug prescriptions.  
**Summary:** There appears to be a greater risk of poor outcome in long-term survivors of stroke with low SBP. This is further evidence that low SBP may result in poor prognosis. |
| Wang WT, et al., 2016 (224) 27082571 | **Aim:** To investigate the relative effects of BP-lowering therapies [ACEI, ARB, BB, CCBs, diuretics, and  
**Inclusion criteria:** RCTs comparing the effects of any of the 6 most commonly used BP-lowering drug classes [ACEI, ARB, alpha-blocker, BB, diuretics, and CCB] vs. placebo  
**1° outcome:** Recurrent stroke  
**2° outcome:** CHD, and MACCE  
**Key findings:**  
• Compared with placebo, ACEI plus diuretic  
• Virtually all BP-lowering medication classes reduced vascular events including recurrent stroke.  
• The higher the average BP reduction between the treatment vs. control groups the larger the risk reduction in recurrent stroke events and MACCE. |
<table>
<thead>
<tr>
<th>Study size: 15 RCTs composed of 39,329 participants previous stroke</th>
<th>or comparing 1 type of antihypertensive agent with another type on pts who have suffered from stroke or TIA s  RCTs reporting outcomes of interest with a follow-up of more than a month.</th>
<th>reduced recurrent stroke (OR: 0.54; 95% CI: 0.33–0.90). ACEI plus diuretic had a higher probability of being at the best ranking position (31%). Compared with regimens not including diuretics, diuretics-based treatments resulted in a significantly larger reduction in BP (12.0 mm Hg; 95% CI: 7.0–16.9). Treatment regimens including diuretics had a RR of 0.619 (95% CI: 0.515–0.743) for recurrent stroke, which was significantly lower than treatments that did not include diuretics (RR=0.882; 95% CI: 0.800–0.973) with a p value for interaction of 0.0008. None of the between-drug comparisons showed significant differences in effect on outcomes.</th>
<th>Diuretic-based treatments lowered the risk of recurrent stroke more than treatments that did not include diuretics. There were no significant differences in effect on 2º stroke reduction between the various individual antihypertensive medication classes.</th>
</tr>
</thead>

| HOPE Östergren J, et al., 2004 (226) 14683738 | **Aim:** To assess the impact of ramipril compared to placebo on the prevention of major CV events in PAD pts in the HOPE study.  
**Study type:** Multicenter, double-blind RCT  
**Size:** 9,541 randomized in HOPE (1,725 randomized who had baseline PAD, defined by ABI with pulse detection by either Doppler or palpation) | **Inclusion criteria:**  
- ≥55 y  
- Existing CVD (CAD, stroke, PAD) or DM with an additional CVD risk factor (smoking, HTN, hypercholesterolemia, low HDL, microalbuminuria)  
- **Exclusion criteria:**  
  - Received ACEI or vitamin E or had uncontrolled HTN  
  - HF or LV dysfunction  
  - All eligible pts had 7- to 10-d run-in period, received 2.5 mg ramipril daily; those who tolerated were then assigned placebo for 10–14 d and then were randomized to 1 of intervention arms or control | **Intervention:** Ramipril (10 mg/d): 4,645 randomized  
**Intervention:** Placebo: 4,652 randomized | **1° endpoint:**  
- Combined CV death, nonfatal MI, nonfatal stroke  
- In pts with history of symptomatic PAD, comparing ramipril to placebo: RR: 0.75; 95% CI: 0.61–0.92  
- In pts with no history of symptomatic PAD, but severe subclinical disease defined as ABI <0.6, comparing ramipril to placebo: RR: 0.77; 95% CI: 0.55–1.09  
- In pts with no history of symptomatic PAD, but moderate subclinical disease defined as ABI 0.6–0.9, comparing ramipril to placebo: RR: 0.72; 95% CI: 0.56–0.92 | **Relevant 2° endpoint:**  
- Individual components of composite endpoint, all-cause mortality, hospitalizations for HF, DM complications  
- In pts with history of symptomatic PAD, comparing ramipril to placebo: for MI, RR: 0.75 (95% CI: 0.58–0.98); for stroke, RR: 0.72 (95% CI: 0.50–1.05); for CVD mortality, RR: 0.75 (95% CI: 0.56–0.99); for total mortality, RR: 0.85 (95% CI: 0.68–1.07); for DM complications, RR: 0.87 (95% CI: 0.74–1.09); for HF, RR: 0.81 (95% CI: 0.53–1.24)  
- In pts with no history of symptomatic PAD, but severe subclinical disease defined as ABI <0.6, comparing ramipril to placebo: for MI, RR: 0.73 (95% CI: 0.48–1.11); for stroke, RR: 0.99 (95% CI: 0.52–1.89); for CVD mortality, RR: 0.76 (95% CI: 0.46–1.25); for total mortality, RR: 0.81 (95% CI: 0.55–1.19); for DM, RR: 0.83 (95% CI: 0.50–1.39); for HF, RR: 0.86 (95% CI: 0.34–1.28)  
- In pts with no history of symptomatic PAD, but moderate subclinical disease defined as ABI 0.6–0.9, comparing ramipril to placebo: for MI, RR: 0.81 (95% CI: 0.60–1.09); for stroke, RR: 0.44 (95% CI: 0.26–0.77); for CVD mortality, RR: 0.62 (95% CI: 0.42–0.90); for total mortality, RR: 0.58 (95% CI: 0.42–0.79); for diabetic complications, RR: 0.80 (95% CI: 0.53–1.21); for HF, RR: 0.69 (95% CI: 0.38–1.23) | **Summary:** Ramipril prevented clinical events in pts with clinical evidence of PAD as well as in those without PAD. The relative benefit was similar in pts classified by levels of ABI, even though event rates were higher in pts with subclinical and clinical ABI. |

### Study Limitations and Adverse Events
Short follow-up, unable to assess hard clinical outcomes

## 2017 Hypertension Guideline Data Supplements

| **Size:** 98 pts | **Inclusion criteria:**
| additional risk factor: DM, hyperlipoproteinemia, total or subtotal vascular occlusion of dilated, segmented, eccentric stenosis, residual stenosis of at least 30%, or stenosis localized in the distal superficial femoral artery | **Intervention arms:**
| Exclusion criteria:  
- History of pelvic stenosis  
- Previous adjuvant therapy with calcium antagonists or beta-adrenergic blocking agents  
- Age >75 y  
- Prior revascularization of same area  
- 1st, 2nd, or 3rd AV block, sinoatrial block, diseases of supporting or connective tissues, moderate arterial HTN with SBP >170 mm Hg and DBP >95 mm Hg  
- Pts requiring stent for large anatomic segments or elastic stenosis | **1° Safety endpoint:** N/A

### Summary:
In pts with PAD at increased risk for restenosis, the administration of high dose verapamil prevented recurrent stenosis for 6 mo after successful peripheral angioplasty and was well tolerated.

- **Crurobrachial ratio tibial artery was 0.76 (SD: 0.09) in verapamil vs. placebo was 0.70 (SD: 0.10)**
- **Arterial pressure was 134/87 mm Hg (SD: 5.2/4.2) in verapamil vs. placebo was 165/97 mm Hg (6.5/4.4), p<0.001**
- **Total vessel diameter was 8.3 mm (SD: 0.3) in verapamil vs. 7.5 mm (SD: 0.3), p<0.001**

### Aim:
Evaluate the effects of treatment with the endothelium-dependent vasodilating beta 1-selective blocker nebivolol, as compared with the nonvasodilating beta 1-selective blocker metoprolol, on clinical parameters of PAD and endothelial function, and to compare the

| Nebivolol (5 mg/d): 65 randomized | **1° endpoint:**
| Change in ABI measured by Doppler  
- In nebivolol: initial ABI 0.62 (SD: 0.16), post-treatment ABI 0.68 (SD: 0.20), p-value for change: 0.002  
- In metoprolol: initial ABI 0.63 (SD: 0.17), post-treatment ABI 0.67 (SD: 0.19) |

| Metoprolol (95 mg/d): 63 randomized | **Relevant 2° endpoint:**
| Change in absolute claudication distance were 32.7 m in nebivolol (p-value 0.03) vs. 39.7 m in metoprolol (p-value 0.01), but no difference between 2 groups (p-value 0.54)  
- Changes in SBP were -5.2 mm Hg in nebivolol (p=0.001) and -3.9 mm Hg in metoprolol (p=0.01), no difference between groups |

---

© 2017 American College of Cardiology Foundation and American Heart Association, Inc.
tolerability of both drugs in pts with PAD

**Study type:** Double-blinded RCT (48 wk)

**Size:** 128

- DBP at time of enrollment <100 mm Hg
- Exclusion criteria:
  - Premenopausal women
  - Critical limb ischemia with rest pain, leg ulcer, gangrene, severe angina pectoris that limits exercise capacity, severe HF that limits exercise capacity, hyperthyroidism, poorly controlled DM (HbA1c>10%)
  - Contraindications for BBs
  - Acute MI within 6 mo before screening
  - Previous treatment with nebivolol or carvedilol
  - Concomitant treatment with calcium antagonists, ACEIs, angiotensin II type 1 receptor antagonists, aspirin, clopidogrel, statins, estrogens was permitted if no change in dosage had been made in the previous 3 mo before screening

0.21), p-value for change: 0.04
- Comparing ABI change in nebivolol to metoprolol: 0.02 (p=0.69).

**1st safety endpoint:** N/A

**Summary:** BB therapy was well tolerated in pts with intermittent claudication and HTN during a treatment period of 1 y. In the direct comparison, there was no significant difference between nebivolol and metoprolol.

**Study limitations and adverse events:**
- Absence of placebo group
- 21 total adverse events, 10 in nebivolol, 11 in metoprolol (adverse events: bradycardia, tachycardia, blurred vision, worsening HTN, edema, worsening claudication, blurred vision, erectile dysfunction, edema, vertigo, temporary dysesthesia of the hands, dyspnea, skin irritation, headache, moderate diarrhea)

**INVEST**
Bavry AA, et al., 2010 (230)

| **Aim:** To examine the effect of average treated BP on adverse outcomes in PAD pts with CAD and to compare 2 antihypertensive medications |
| **Study type:** Post hoc analysis of international Inclusion criteria: |
| ≥50 y | HTN, clinically stable CAD |
| Pt reported PAD |

| **Exclusion criteria:** |
| Contraindications to the treatment groups |
| *2º medications only given to achieve BP of |

| **Interventions:** |
| Calcium antagonist-based strategy: verapamil with or without trandolapril |
| BB-based strategy: atenolol with or without hydrochlorothiazide |

| **1º endpoint:** |
| Composite outcome: all-cause death, nonfatal MI, nonfatal stroke |
| No statistically significant difference in composite 1º outcome OR: 0.90 (95% CI: 0.76, 1.07) comparing calcium antagonist based group to BB based group in fully adjusted model |

**Relevant 2º endpoint:** N/A

**Study limitations and adverse events:**
- No change in flow-mediated dilatation in either group (p=0.16)
- Absence of placebo group
- 21 total adverse events, 10 in nebivolol, 11 in metoprolol (adverse events: bradycardia, tachycardia, blurred vision, worsening HTN, edema, worsening claudication, blurred vision, erectile dysfunction, edema, vertigo, temporary dysesthesia of the hands, dyspnea, skin irritation, headache, moderate diarrhea)

### Thompson AM, et al., 2011 (113) 21364140

| Aim: To evaluate the effect of antihypertensive treatment on secondary prevention of CVD events and all-cause mortality among pts | Inclusion criteria: RCTs of antihypertensive treatment among pts with BP <140/90 mm Hg for the prevention of CVD events. | Interventions: Any antihypertensive agent compared with placebo or no treatment. | Results: Compared with controls, pts receiving antihypertensive medications had a pooled RR of 0.77 (95% CI: 0.61, 0.77) for stroke: 0.80 (95% CI: 0.69, 1.00) | Relevant 2° endpoint: PAD not specifically collected at baseline, thus cannot detect actual incidence (however, randomization presumably resulted in equal number of baseline PAD cases in each group) | Study limitations and adverse events: PAD not specifically collected at baseline, thus cannot detect actual incidence (however, randomization presumably resulted in equal number of baseline PAD cases in each group) |
without clinically defined HTN.

**Study type:** Meta-analysis including 25 RCTs

**Size:** 64,162 pts without HTN.

**Exclusion criteria:** CVD events were not reported by HTN status that included participants with and without HTN; study population did not include persons with BP in the normal or prehypertensive ranges; study population did not include persons with preexisting CVD or CVD equivalents, such as DM; antihypertensive medication was not a part of the intervention; treatment allocation was not random; measure of variance not reported; participants were <18 y; there were differences between intervention and control groups other than antihypertensive treatment. Preexisting CVD included PAD.

**Results:**
- 0.93) for MI: 0.71 (95% CI: 0.65, 0.77) for CHF: 0.85 (95% CI: 0.80, 0.90) for composite CVD events: 0.83 (95% CI: 0.69, 0.99) for CVD mortality and 0.87 (95% CI: 0.80, 0.95) for all-cause mortality from random effect models. Results did not differ according to trial characteristics or subgroups defined by clinical history, although no specific PAD subgroup was defined.

**Summary:** Among pts with clinical history of CVD, including PAD, but without HTN, antihypertensive treatment was associated with reduced risk of stroke, CHF, composite CVD events and all-cause mortality.

**DM irrespective of initial BP levels or the use of other BP-lowering drugs.**

**Study type:** RCT  
**Size:** 11,140 pts, 4.3 y follow-up

- Revascularization, or amputation for PVD) or at least 1 other risk factor (history of microvascular disease, microalbuminuria, proliferative diabetic retinopathy, retinal photocoagulation therapy, macular edema, blindness, cigarette smoking, high cholesterol, low HDL cholesterol, diagnosis of DM at least 10 y before enrollment or ≥65 y at entry

**Exclusion criteria:** HbA1c target ≤6.5% or indication for insulin.

- Vascular events decreased by 9% (HR: 0.91; (95% CI: 0.83, 1.00), p<0.04). Death from CVD decreased by 18%; RR: 0.82 (95% CI: 0.68, 0.98) and death from any cause decreased by 14%; RR: 0.86 (95% CI: 0.75, 0.98). The effects of study treatment did not differ by initial BP or concomitant use of other treatments at baseline. The pts had at least 1 CV risk factor.

---

**The ADVANCE trial included DM pts both with and without HTN. In this RCT, pts were randomized to active treatment or placebo rather than to a different BP goal, so that it is impossible to determine whether the benefit was due to the treatment of HTN per se.**

---

**ACCORD**  
Cushman WC, et al., 2010 (234)  
20228401

**Aim:** To assess whether therapy targeting normal SBP (<120 mm Hg) reduces major CV events in DM-2 at high risk for CV events.  
**Study type:** RCT  
**Size:** 4,733 pts, 4.7 y follow-up

**Inclusion criteria:** DM-2 with HgbA1c ≥7.5%; ≥40 y with CVD or ≥55 y with anatomical evidence of atherosclerosis, albuminuria, LVH, or ≥2 additional risk factors for CVD.

**Exclusion criteria:** BMI ≥45, serum creatinine >1.5, and other serious illness.

- Pts were randomly assigned to intensive therapy SBP <120 mm Hg or standard therapy SBP <140 mm Hg.

**1° outcomes:** Nonfatal MI, nonfatal stroke, or CV death.

**Results:** Mean SBP in the intensive therapy group was 119.3 mm Hg and in the standard therapy group was 133.5 mm Hg. The annual 1° outcomes 1.87% in the intensive therapy group and 2.09% in the standard therapy group HR: 0.88; 95% CI: 0.073–1.06; p=0.20. The annual rates of death from any cause were 1.28% and 1.19% in the 2 groups, respectively (HR: 0.59; 95% CI: 0.39–0.89; p=0.01). Serious adverse events attributed to antihypertensive treatment occurred in 3.3% of the intensive therapy group and 1.3% of the standard therapy group (p<0.001).

**Limitations:** This trial had an open label design. The rate of adverse events in the standard therapy group was less than expected. Pts younger than 40 y or older than 79 y were not included.

**Summary:** In pts with DM-2 and high risk for CV events, targeting SBP of <120 as compared with <140 mm Hg did not reduce the rate of composite outcome of fatal and nonfatal major CV events and was associated with greater risk for adverse events.
### Margolis KL et al., 2014 (235) 24595629

**Aim:** To compare effects of combinations of standard and intensive treatment of glycemia and BP in the ACCORD trial.

**Study type:** RCT

**Size:** 4,733 pts, 4.7 y follow-up

#### Inclusion criteria:
Type 2 DM with HgbA1c ≥7.5%; ≥40 y with CVD or ≥55 y with anatomical evidence of atherosclerosis, albuminuria, LVH, or at least 2 additional risk factors for CVD.

#### Exclusion criteria:
BMI ≥45, serum creatinine >1.5, and other serious illness.

- **Pts were randomly assigned to intensive therapy SBP<120 mm Hg or standard therapy SBP<140 mm Hg.**

#### 1° outcomes: Nonfatal MI, nonfatal stroke, or CV death.

**Results:** In the BP trial, risk of the 1° outcome was lower in the groups intensively treated for glycemia HR: 0.67 (95% CI: 0.50, 0.91), BP HR: 0.74 (95% CI: 0.55, 1.00), or both HR: 0.71 (95% CI: 0.52, 0.96) compared with combined standard BP and glycemia treatment. For 2° outcomes, MI was significantly reduced by intensive glycemia treatment and stroke by intensive BP treatment; most other HRs were neutral or favored intensive treatment groups.

#### Limitations:
2° analysis; results analyzed across individual cells of a factorial design with shorter follow-up than originally intended reducing power to detect meaningful differences and interactions; results may not apply to younger, healthier diabetics.

**Conclusions:** Either intensive BP or glycemia control reduced major CVD compared with combined standard treatment, but the combination was no better than the individual intensive interventions.

### Soliman EZ et al., 2015 (236) 26459421

**Aim:** To compare effects of combinations of standard and intensive control of BP on the risk of LVH in the ACCORD trial.

**Study type:** RCT

**Size:** 4,331 pts, 4.7 y follow-up

#### Inclusion criteria:
DM-2 with HgbA1c ≥7.5%; ≥40 y with CVD or ≥55 y with anatomical evidence of atherosclerosis, albuminuria, LVH, or at least 2 additional risk factors for CVD.

#### Exclusion criteria:
BMI ≥45, serum creatinine >1.5, and other serious illness.

- **Pts were randomly assigned to intensive therapy SBP<120 mm Hg or standard therapy SBP<140 mm Hg.**

#### 1° outcomes: Nonfatal MI, nonfatal stroke, or CV death.

**Results:** The outcome measures were electrocardiographic LVH defined by Cornell voltage (binary variable) and mean Cornell index (continuous variable). The baseline prevalence of LVH (5.3% vs. 5.4%; p=0.91) and the mean Cornell index (1,456 vs. 1,470 µV; p=0.45) were similar in the intensive (n=2,154) and standard (n=2,177) BP-lowering arms, respectively. However, after median follow-up of 4.4 y, intensive, compared with standard, BP lowering was associated with a 39% lower risk of LVH (OR: 0.61; 95% CI: 0.43–0.88; p=0.008) and a significantly lower adjusted mean Cornell index (1.352 vs. 1.447 µV; p<0.001). The lower risk of LVH associated with intensive BP lowering during follow-up was because of more regression of baseline LVH and lower rate of developing new LVH, compared with standard BP lowering. No interactions by age, sex, or race were observed.

#### Limitations:
2° analysis; open-label design; LVH defined by EKG and not by echo or cardiac MRI; results may not apply to younger, healthier diabetics.

**Conclusions:** Targeting a SBP of <120 mm Hg when compared with <140 mm Hg in pts with HTN and DM produces a greater reduction in LVH.
<table>
<thead>
<tr>
<th>Xie X, et al., 2015 (21)</th>
<th><strong>Aim:</strong> To assess the efficacy and safety of intensive BP lowering strategies.</th>
</tr>
</thead>
</table>

**Study type:** Systematic review and meta-analysis

**Size:** 19 trials with 44,989 pts; 3.8 y of follow-up.

**Inclusion criteria:** RCTs with different BP targets or different BP changes between more vs. less intense therapy with at least 6 mo follow-up.

**Exclusion criteria:** Trials that did not assess a different target or relevant outcome.

- 5 RCTs (6,960 pts) enrolled only pts with DM and 6 trials (2,809 pts) specifically recruited pts with CKD.

**1^ outcomes:** Major CV events, defined as MI, stroke, HF or CV death, separately and combined; nonvascular and all-cause mortality; ESKD; and adverse events; new onset microalbuminuria/macroalbuminuria or change from micro- to macroalbuminuria and retinopathy in pts with DM.

**Results:** Pts in the more intensive BP-lowering treatment group had mean BP 133/76 mm Hg compared with 140/81 mm Hg in the less intensive group. Intensive BP-lowering treatment achieved RR reductions for major CV events: 14% (95% CI: 4–22), MI: 13% (95% CI: 0–24), stroke: 22% (95% CI: 10–32), albuminuria: 10% (95% CI: 3–16), and retinopathy progression: 19% (95% CI: 0–34). However, more intensive treatment had no clear effects on HF: RR: 15% (95% CI: -11–34), CV death: 9% (-11–26), total mortality: 9% (95% CI: -3–19), or ESKD: 10% (95% CI: -6–23). The reduction in major CV events was consistent across pt groups, and additional BP lowering had a clear benefit even in pts with SBP <140 mm Hg. The absolute benefits were greatest in trials in which all enrolled pts had vascular disease, renal disease or DM. Serious adverse events associated with BP lowering were only reported by 6 trials and had an event rate of 1%–2% per y in intensive BP lowering group pts, compared with 0.9% in the less intensive treatment group (RR: 1.35; 95% CI: 0.93–1.97). Severe hypotension was more frequent in the more intensive treatment regimen (RR: 2.68; 95% CI: 1.21–5.89; p=0.015), but the absolute excess was small (0.3% vs. 0.1% per pt-y for the duration of follow-up).

**Study limitations:** Only 6,960 pts with DM were included in the total study size of 44,989 pts.

**Conclusions:** The absolute CV benefits were greatest in trials in which all enrolled pts had vascular disease, renal disease or DM. However, only 6,960 of the 44,989 pts had DM and no sub-analysis for DM was provided; however, the outcome benefits were qualitatively most striking for pts with DM, CKD and/or vascular disease.

### ROADMAP

**Menne J, et al., 2012 (240) 22418908**

**Aim:** To assess whether olmesartan compared to placebo delays the onset of albuminuria in pts with DM and HTN.

**Study type:** RCT

**Size:** 4,020 pts; follow-up 3.2 y

**Inclusion criteria:** Pts with HTN defined as BP ≥130/80 mm Hg and at least 1 CV risk factor.

• Pts were randomly assigned to olmesartan or placebo. Additional antihypertensive therapy except for ACEs and ARBs to lower BP.

**1° outcome:** Time to onset of microalbuminuria.

**Results:** Average BP was 126.3/74.7 and 129.5/76.6, respectively (significant not stated). Olmesartan delayed the onset of microalbuminuria by 25% (0.75; 95% CI: 0.61–0.92; p=0.007). CV events were comparable in the 2 groups.

**Summary:** Pts with better BP reduction are less likely to develop microalbuminuria. Treatment with an ARB delayed the onset of microalbuminuria independently of baseline BP and degree of BP reduction.

### ABCD

**Estacio RO, et al., 1998 (241) 9486993**

**Aim:** To compare the effects of "intensive" compared with "moderate" BP treatment on 24-h creatinine clearance (GFR) in pts with DM and HTN.

**Study type:** RCT – open label

**Size:** 472 pts; follow-up 5 y

**Inclusion criteria:** Pts with HTN defined as DBP ≥90 mm Hg and DM-2

• Pts were randomly assigned to "intensive" treatment (DBP <75 mm Hg and "moderate" treatment (DBP 80–89 mm Hg) with a combination of nisoldipine and enalapril as the initial antihypertensive medication.

**1° outcome:** Change in 24-h creatinine clearance.

**Results:**
- The mean BP achieved was 132/78 in the intensive group and 138/86 in the moderate control group. During the 5-y follow-up period, there was no difference in GFR between the groups. After the first y of antihypertensive treatment, GFR stabilized in both the intensive and moderate groups with normal albumin excretion or microalbuminuria. In contrast, pts with overt albuminuria demonstrated steady decline in GFR whether on intensive or moderate therapy. Neither was there a significant difference in the progression from normal to micro- or micro-to overt albuminuria.
- Intensive therapy demonstrated a lower overall incidence of deaths, 5.5% vs. 10.7%; p=0.037 (2° endpoint).

**Limitations:** Open-label design; the definition of DM was 2 fasting blood glucose measurements >140 mg/dL as opposed to >126 today; serious side effects were not reported. Risk of bias due to a greater proportion of pts with established CVD at baseline assigned to the standard BP target.

**Summary:** BP control of 138/86 or 132/78 with either nisoldipine or enalapril as the initial antihypertensive agent appeared to stabilize renal function in HTN pts with type 2 DM without overt albuminuria over a 5-y period. For the ABCD trials, only ABDC (H) included strictly pts with HTN and DM. The quality of evidence is low due to imprecision and risk of bias.

### Hypertension Optimal Treatment (HOT trial)

**Aim:** To assess the optimum target DBP

**Inclusion criteria:** Pts with HTN defined as

• Pts were randomly assigned to 1 of 3 DBP target

**1° outcomes:** Major CV events, MI, stroke, CV mortality and total mortality.

**Limitations:** Open-label design; the definition of DM-2 fasting blood glucose measurements >140 mg/dL

<td>2017 Hypertension Guideline Data Supplements</td>
<td>1998 (243)</td>
<td>1,148 hypertensive pts with type 2 DM</td>
<td>Fasting plasma glucose concentration &gt;6 mmol/l in 2 mornings.</td>
<td>Ketonuria &gt;3 mmol/l; history of MI in the previous y; current angina or HF; &gt;1 major vascular episode; serum creatinine concentration &gt;175 μmol/l; retinopathy requiring laser treatment; malignant HTN; an uncorrected endocrine abnormality; an occupation that would preclude insulin treatment; a severe concurrent illness; inadequate understanding or unwillingness to enter the study.</td>
<td>Pts were randomized to tight BP control (target BP&lt;150/85 mm Hg) or less tight BP control (target &lt;180/105 mm Hg).</td>
<td>1° outcomes:</td>
<td>BP in the tight BP control group was 144/82 compared with the group assigned less tight control (154/87), p&lt;0.0001. Reductions in risk in the group assigned tight BP control compared with those of the less tight control group were 24% (95% CI: 8%–38%; p=0.0046) in DM related endpoints; 32% in deaths related to DM (95% CI: 6%–51%; p&lt;0.019; 44% in strokes (95% CI: 11%–65%; p&lt;0.013; and 37% (95% CI: 11%–36%; p&lt;0.0092 in microvascular endpoints, predominantly due to risk of retinal photocoagulation.</td>
<td>DBP targets were high (85 mm Hg in the tight control group and 105 mm Hg in the less tight control group) and similar to the cutoffs for the no treatment groups in trials comparing treatment with no treatment. UKPDS evaluated lowering both SBP and DBP so it is impossible to separate the outcomes effects of DBP. Therefore, the evidence is of low quality.</td>
<td>Summary: Tight BP control in pts with HTN and DM-2 achieved a clinically important reduction in the risk of death related to DM, complications related to DM, progression of DM retinopathy and deterioration of visual acuity, but the quality of evidence is low.</td>
</tr>

| Arguedas JA, et al., 2013 (244) | 24170669 | 2017 Hypertension Guideline Data Supplements | 2013 (244) | RCTs in which individuals were | | | | | | Evidence from RCTs does not support BP targets lower than 130/85. | Conclusions: Evidence from RCTs does not support BP targets lower than 130/85.
mm Hg) are associated with reduction in mortality and morbidity compared to "standard" BP targets (<140–160/90–100 mm Hg) in pts with DM.

**Study type**: Meta-analysis of RCTs.

**Size**: 5 RCTs recruiting a total of 7,314 ps.

**Mean follow-up**: 4.5 y

randomized to a "lower" compared with a "standard" BP target.

**Exclusion criteria**: Studies that did not meet the inclusion criteria. Excluded studies were UKPDS 1998, HTN in Diabetes Study IV 1996, SANDS 2008, Lewis 1999 and the Steno-2 study.

**Results**: Only 1 trial (ACCORD) compared outcomes associated with 'lower' (<120 mm Hg) or 'standard' (<140 mm Hg) SBP targets in 4734 pts. Despite achieving a significantly lower BP (119.3/64.4 mm Hg vs. 133.5/70.5 mm Hg, p<0.0001), and using more antihypertensive medications, the only significant benefit in the group assigned to 'lower' SBP was a reduction in the incidence of stroke: RR: 0.58; (95% CI: 0.39–0.88; p=0.009), absolute risk reduction 1.1%. The effect of SBP targets on mortality was compatible with both a reduction and increase in risk: RR: 1.05 (95% CI: 0.84, 1.30), low quality evidence. Trying to achieve the 'lower' SBP target was associated with a significant increase in the number of other serious adverse events: RR: 2.58, (95% CI: 1.70–3.91; p<0.00001, absolute risk increase 2.0%. 4 trials (ABCD-H, ABCD-N, ABCD-2V, and a subgroup of HTN Optimal Treatment) specifically compared clinical outcomes associated with 'lower' vs. 'standard' targets for DBP in pts with DM. The total number of pts included in the DBP target analysis was 2580. Pts assigned to 'lower' DBP had a significantly lower achieved BP: 128/76 mm Hg vs. 135/83 mm Hg; p<0.0001. There was a trend towards reduction in total mortality in the group assigned to the 'lower' DBP target: RR: 0.73 (95% CI: 0.53–1.01), mainly due to a trend to lower non-CV mortality. There was no difference in stroke: RR: 0.67, (95% CI: 0.42–1.05), in MI: RR: 0.95 (95% CI: 0.64–1.40) or in CHF: RR: 1.06 (95% CI: 0.58–1.92), low-quality evidence. End-stage renal failure and total serious adverse events were not reported in any of the trials. A sensitivity analysis of trials comparing DBP targets <80 mm Hg (as suggested in clinical guidelines) than standard targets in pts with HTN and DM.

<td><strong>Limitations:</strong> No analysis of renal outcomes, risk of new DM or progression of existing DM; combined comparison of persons taking diuretics and BBs; some studies selected pts on the basis of the presence or absence of DM.</td>
<td><strong>Summary:</strong> Effects of BP-lowering agents on major CV events were broadly comparable for pts with and without DM.</td>
</tr>
</tbody>
</table>
**Size:** 27 RCTs including 158,709 pts (33,395 with DM and 125,314 without DM).

**Follow-up:** Minimum 1,000 pt-y

**Aim:** To determine the optimal first step antihypertensive drug therapy in DM-2 or impaired fasting blood glucose levels and specifically whether treatment with a CCB or ACEI decreases clinical complications compared to treatment with a thiazide type diuretic.

**Study type:** RCT

**Size:** 31,512 pts stratified into type 2 DM (13,101), IFG (1,399) and normoglycemia (17,012)

**Inclusion criteria:** Pts ≥55 y with HTN and at least 1 other risk factor for CHD.

**Exclusion criteria:** No history of DM or no fasting glucose measurement or nonfasting glucose level ≥110 mg/dL.

**Pts were randomly assigned to double-blind first-step treatment with chlorthalidone 12.525 mg/d, amiodipine 2.5–10 mg/d or Lisinopril 10–40 mg/d.**

**1° outcomes:** Fatal CHD and nonfatal MI

**Results:** There was no significant difference in RR (RR) for the 1° outcome in DM or NG pts assigned to amiodipine or lisinopril vs. chlorthalidone or in IFG pts assigned to lisinopril vs. chlorthalidone RR: 1.73 (95% CI: 1.10, 2.72). A significantly higher RR was noted for the 1° outcome in IFG pts assigned to amiodipine vs. chlorthalidone. Stroke was more common in NG pts assigned to lisinopril vs. chlorthalidone RR: 1.31 (95% CI: 1.10, 1.57). HF was more common in DM and NG pts assigned to amiodipine RR: 1.39 (95% CI: 1.22, 1.59) and 1.30 (95% CI: 1.12, 1.51), respectively or lisinopril: 1.15 (95% CI: 1.00–1.32) and 1.19 (95% CI: 1.02, 1.39), respectively vs. chlorthalidone.

**Limitations:** Microalbuminuria was not measured.

**Summary:** Our results provide no evidence of superiority for treatment with CCBs or ACEIs compared with a thiazide-type diuretic during first-step antihypertensive therapy in DM, IFG, or NG.

treatment and presence of vascular disease in DM-2

**Study type:** Large meta-analysis of 40 high quality RCTs (1/1966–10/2014) judged low risk of bias

**Size:** 100,354 pts with DM; all trials >1,000 pt-y of follow-up

BP-lowering drug vs. placebo:
- More intensive vs. less intensive BP lowering: 7 RCTs
- BP-lowering vs. another drug: 17 RCTs

which entire trial population had DM-2 or in which the results of a DM subgroup were obtained. Studies were included regardless of the presence or absence of defined HTN.

**Exclusion criteria:** Trials conducted predominantly in pts with type 1 DM were excluded.

**Results:** Baseline BP: A 10-mm Hg SBP reduction was associated with a significantly lower risk of all-cause mortality RR: 0.87 (95% CI: 0.78–0.96), CVD events RR: 0.89 (95% CI: 0.80–0.98), and stroke events RR: 0.73 (95% CI: 0.64–0.83). The associations for HF and renal failure were not significant. For microvascular events, a 10-mm reduction in SBP was associated with a lower risk of retinopathy RR: 0.87 (95% CI: 0.76–0.99) and albuminuria RR: 0.83 (95% CI: 0.79–0.87).

**Stratified by initial SBP:**
Trials stratified by SBP >140 to <140 mm Hg showed significant interactions for all-cause mortality RR: 0.73 (95% CI: 0.64–0.84) vs. 1.07 (95% CI: 0.92–1.26), CVD RR: 0.74 (95% CI: 0.65–0.85) vs. RR: 0.96 (95% CI: 0.88–1.05), CHD RR: 0.73 (95% CI: 0.61–0.87) vs. RR: 0.97 (95% CI: 0.86–1.10), HF RR: 0.75 (95% CI: 0.59–0.94) vs. RR: 0.97 (95% CI: 0.79–1.19) and albuminuria RR: 0.71 (95% CI: 0.63–0.79) vs. RR: 0.86 (95% CI: 0.81–0.99).

**Stratified by achieved SBP:**
Trials stratified by SBP achieved in the treatment group ≥130 or <130 mm Hg and the associations of a 10-mm Hg SBP reduction compared between the strata showed significant interactions for all-cause mortality RR: 0.75 (95% CI: 0.65–0.86) vs. RR: 1.06 (95% CI: 0.90–1.265), CVD RR: 0.74 (95% CI: 0.64–0.85) vs. RR: 0.96 (95% CI: 0.88–1.05), CHD RR: 0.70 (95% CI: 0.58–0.83) vs. RR: 0.97 (95% CI: 0.85–1.10), HF achieved SBP levels in the 120–130 mm Hg range. The relatively short follow-up of included trails may have prevented associations of BP-lowering treatment with vascular outcomes from being observed, particularly for outcomes such as HF and renal failure, which are often a consequence of MI or albuminuria, respectively.

**Summary:**
- This large meta-analysis of 40 RCTs provides evidence that BP lowering is associated with lower risks of outcomes in pts with initial mean SBP ≥140 mm Hg compared with those <140 mm Hg with the exception of stroke, albuminuria and retinopathy. When trials were stratified by achieved SBP treatment was associated with lower risks only in the <130 mm Hg stratum for stroke and albuminuria.
- This meta-analysis shows that although BP lowering was not associated with a lower risk of CVD or CHD events at a baseline SBP <140 mm Hg, it does observe lower risks of stroke, retinopathy and progression of albuminuria.
- This study provides evidence that for individuals at high risk for these outcomes (history of cerebrovascular disease or mild nonproliferative retinopathy), commencement of therapy below an initial SBP of 140 mm Hg and treatment to SBP <130 may be indicated.
**Aim:** To determine if “lower” BP targets (any target <130/85 mm Hg) are associated with reduction in mortality and morbidity compared to “standard” BP targets (<140–160/90–100 mm Hg) in pts with DM.

**Study type:** Meta-analysis of RCTs.

| **Inclusion criteria:** RCTs in which individuals were randomized to a “lower” compared with a “standard” BP target. |
| **Exclusion criteria:** Studies that did not meet the inclusion criteria. Excluded studies were UKPDS 1998, HTN in Diabetes Study IV |

**1st outcomes:** Total mortality, total serious adverse events, MI, stroke, CHF, and ESRD.

**Results:** Only 1 trial (ACCORD) compared outcomes associated with ‘lower’ (<120 mm Hg) or ‘standard’ (<140 mm Hg) SBP targets in 4734 pts. Despite achieving a significantly lower BP (119.3/64.4 mm Hg vs. 133.5/70.5 mm Hg, p<0.0001), and using more antihypertensive medications, the only significant benefit in the group assigned to ‘lower’ SBP was a reduction in the incidence of HTN in Diabetes Study IV.

**Conclusions:** Evidence from RCTs does not support BP targets lower than standard targets in pts with HTN and DM.

The effect of SBP targets on mortality was compatible with both a reduction and increase in risk: RR: 1.05 (95% CI: 0.84–1.30), low-quality evidence. Trying to achieve the 'lower' SBP target was associated with a significant increase in the number of other serious adverse events: RR: 2.58 (95% CI: 1.70–3.91; p<0.00001), absolute risk increase 2.0%. 4 trials (ABCD-H, ABCD-N, ABCD-2V, and a subgroup of HOT) specifically compared clinical outcomes associated with 'lower' vs. 'standard' targets for DBP in pts with DM. The total number of pts included in the DBP target analysis was 2580. Pts assigned to 'lower' DBP had a significantly lower achieved BP: 128/76 mm Hg vs. 135/83 mm Hg, p<0.0001. There was a trend towards reduction in total mortality in the group assigned to the 'lower' DBP target: RR: 0.73 (95% CI: 0.53–1.01), mainly due to a trend to lower non-CV mortality. There was no difference in stroke: RR: 0.67 (95% CI: 0.42–1.05), in MI: RR: 0.95 (95% CI: 0.64–1.40) or in CHF: RR: 1.06 (95% CI: 0.58–1.92), low-quality evidence. End-stage renal failure and total serious adverse events were not reported in any of the trials. A sensitivity analysis of trials comparing DBP targets <80 mm Hg (as suggested in clinical guidelines) vs. <90 mm Hg showed similar results. There was a high risk of selection bias for every outcome analyzed in favor of the 'lower' target in the trials included for the analysis of DBP targets.

**Aim:** To assess whether therapy targeting normal SBP (<120 mm Hg) reduces major of stroke: RR: 0.58 (95% CI: 0.39–0.88; p=0.009), absolute risk reduction 1.1%. The effect of SBP targets on mortality was compatible with both a reduction and increase in risk: RR: 1.05 (95% CI: 0.84–1.30), low-quality evidence. Trying to achieve the 'lower' SBP target was associated with a significant increase in the number of other serious adverse events: RR: 2.58 (95% CI: 1.70–3.91; p<0.00001), absolute risk increase 2.0%. 4 trials (ABCD-H, ABCD-N, ABCD-2V, and a subgroup of HOT) specifically compared clinical outcomes associated with 'lower' vs. 'standard' targets for DBP in pts with DM. The total number of pts included in the DBP target analysis was 2580. Pts assigned to 'lower' DBP had a significantly lower achieved BP: 128/76 mm Hg vs. 135/83 mm Hg, p<0.0001. There was a trend towards reduction in total mortality in the group assigned to the 'lower' DBP target: RR: 0.73 (95% CI: 0.53–1.01), mainly due to a trend to lower non-CV mortality. There was no difference in stroke: RR: 0.67 (95% CI: 0.42–1.05), in MI: RR: 0.95 (95% CI: 0.64–1.40) or in CHF: RR: 1.06 (95% CI: 0.58–1.92), low-quality evidence. End-stage renal failure and total serious adverse events were not reported in any of the trials. A sensitivity analysis of trials comparing DBP targets <80 mm Hg (as suggested in clinical guidelines) vs. <90 mm Hg showed similar results. There was a high risk of selection bias for every outcome analyzed in favor of the 'lower' target in the trials included for the analysis of DBP targets.

**Inclusion criteria:** Type 2 DM with HgbA1c ≥7.5%; ≥40 y with CVD or ≥55 y with anatomical evidence of

**Pts were randomly assigned to intensive therapy SBP<120 mm Hg or standard therapy SBP<140 mm Hg.**

**Limitations:** This trial had an open label design. The rate of adverse events in the standard therapy group was less than...

<tr>
<td>• BP targets varied substantially between trials. 2 trials targeted mean BP &lt;92 mm Hg for the intensive treatment arm, and 107 mm Hg in the standard treatment arm. 1 trial aimed for BP &lt;130/80 mm Hg vs. a DBP of 90 mm Hg, 1 study targeted &lt;120/80 mm Hg vs. 135–140/85–90 mm Hg, and 4 studies had DBP &lt;75–80 mm Hg vs. from 80–90 mm Hg. A trial involving pediatric pts targeted a 24-h mean BP &lt;the 50th percentile, compared with the 50th to 95th percentiles in the control group. 2 trials had more liberal targets for intensive treatment (&lt;140–150 mm Hg SBP, 85 mm Hg DBP)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>difference in DBP seen between treatment arms. Overall, a more intensive regimen reduced risk of composite kidney failure events by 17% (HR: 0.82; 95% CI: 0.68, 0.98), reduced the risk of ESKD alone by 18% (pooled HR for composite outcomes: 0.79; 95% CI: 0.67, 0.93).</td>
<td></td>
<td></td>
</tr>
<tr>
<td>• Intensive BP lowering had no effect on kidney failure in pts who did not have proteinuria (3 trials involving 1,218 pts (HR: 1.12; 95% CI: 0.67–1.87), but it did reduce the risk of progressive kidney failure by 27% (5 trials involving 1,703 pts (HR: 0.73; 95% CI: 0.62–0.86) in pts who did have proteinuria at baseline.</td>
<td></td>
<td></td>
</tr>
<tr>
<td>• CV outcomes: major CV events reported in 5 trials (472 CV events in 5,308 pts with CKD). Intensive BP lowering did not reduce risk of CV events in pts with CKD, but the CIs remained wide (RR: 1.09 (95% CI: 0.83, 1.42). 6 trials reported stroke outcomes (197 events in 5,411 pts), 5 trials reported MI (138 events in 4,317 pts), and 5 trials reported HF (118 events in 5,308 pts). They saw no clear effect of intensive treatment on any of these vascular outcomes.</td>
<td></td>
<td></td>
</tr>
<tr>
<td>• Death: 10 trials involving 6,788 pts reported 846 deaths. There was no clear effect of intensive BP lowering on risk of all-cause death (RR: 0.94 (95% CI: 0.84, 1.05) or CV death (RR: 1.20 (95% CI: 0.82, 1.75).</td>

<td></td>
</tr>
</tbody>
</table>
### SEAS

**Rieck ÅE**  
Hypertension, 2012 (263) 22647889

**Aim:** To determine the impact of HTN on LV structure and outcome during progression of aortic valve stenosis  
**Study type:** RCT observational substudy of SEAS trial  
**Size:** 1616 pts  
**Intervention:** 1,340 pts with HTN  
**Comparator:** 276 pts without HTN  
**Inclusion criteria:** Pts 45-85 y who had asymptomatic, mild-to-moderate aortic valve stenosis, as assessed on echo, with a peak aortic-jet velocity of 2.5–4 m per second, were eligible for the study.  
**1° endpoint:** Echo LV mass; MACE; mortality  
- HTN predicted 51% higher incidence of abnormal LV geometry at final study visit independent of other confounders (p<0.01).  
- HTN was associated with a 56% higher rate of ischemic CV events and a 2-fold increased mortality (both p<0.01).  
- No specific randomized intervention for HTN.

### Eleid MF, et al., 2013 (264) 23956211

**Aim:** To evaluate the hemodynamic effects of vasodilator therapy in pts with LGSAS  
**Study type:** Nitroprusside infusion  
**Size:** 24  
**Intervention:** Infusion of IV sodium nitroprusside to reduce BP and arterial afterload (18 pts with hypertensive LGSAS)  
**Comparator:** Baseline hemodynamics (6 pts with low EF LGSAS)  
**Exclusion criteria:** Moderate or severe concomitant valvular disease (e.g., aortic, mitral or tricuspid regurgitation), reduced left ventricular EF (>50%), age <18 y, and complex CHD.  
**1° endpoint:** Nitroprusside reduced mean PA pressure (25±10 mm Hg) and LV end-DBP (11±5 mm Hg; p<0.001 for both compared with baseline).  
- Treatment of HTN with vasodilator therapy results in a lowering of the total LV afterload, with a decrease in LV filling pressures and PA pressures.  
- No translation to clinical or ambulatory vasodilator use.

### RIAS Trial  

**Bull S, et al., 2015 (265) 25796267**

**Aim:** To determine if ACEIs improve outcomes in AS.  
**Study type:** RCT  
**Size:** 100  
**Intervention:** Ramipril ramped up from 2.5 to 5 to 10 mg for 1 y (50 pts)  
**Comparator:** Placebo (50 pts)  
**Inclusion criteria:** Pts >18 y with moderate or severe aortic stenosis (valve area <1.5 cm², or peak velocity >3.0 m/s [peak valve gradient >36 mm Hg]), 2 who were asymptomatic as judged by pt-reported symptoms,  
**1° endpoint:** Adverse events; laboratory abnormalities; change in LVM from baseline to 12 mo measured by CMR.  
- Reduction in LVM in the ramipril group vs. placebo group (mean change -5.9 vs. +4.5 g, respectively; p=0.0057); preserved tissue Doppler systolic velocity compared with placebo (+0.0 vs. -0.5 cm/s).  
- No specific randomized intervention for HTN.

<td>CKD outcomes: Summary: More intensive SBP lowering to a goal of &lt;120 mm Hg with achieved mean of ~121 mm Hg resulted in less CVD and lower total mortality over 3.26 y in comparison with a goal SBP&lt;140 mm Hg and achieved SBP of ~135 mm Hg. There were small increases in some expected SAEs. Perhaps unexpected, a sizable</td>
</tr>
</tbody>
</table>
Size: 9361 participants followed median of 3.26 y

Framingham General CVD risk≥15% in 10 y

Exclusion criteria: Major ones included DM, history of stroke, ESRD (eGFR <20)

During the trial, mean SBP was 121.5 vs. 134.6.

1° in CKD pts: reduction in GFR of ≥50% or ESRD 0.89 (0.42–1.87)

Incident albuminuria: 0.72 (0.48–1.07)

In pts without CKD: reduction in GFR ≥30% and to <60 3.49 (2.44–5.10)

Incident albuminuria: 0.81 (0.63–1.04)

Adverse events:

SAEs: 1.04; p=0.25

Significant absolute increases seen in intensive group for hypotension (1%), syncope (0.6%), electrolyte abnormality (0.8%), acute kidney injury/acute renal failure (1.6%) over the study period.

1.7% fewer pts had orthostatic hypotension in intensive group; p=0.01.

VA Coop 1967 (262) 4862069

Study type: RCT to examine effect of treatment of severe HTN

Size: 143

54% African American

DBP 115–129 mm Hg

HCTZ, Reserpine, Hydralazine vs. placebo

CVD or stroke events, Grade 3 or 4 retinopathy, doubling of creatinine or BUN. Study terminated early for 27 events vs. 2 events (placebo vs. active)

N/A

VA Coop 1970 (271) 4914579

Study type: RCT to examine effect of treatment of mild to moderately severe HTN

Size: 380

42% African American

DBP 90–115 mm Hg

HCTZ, Reserpine, Hydralazine vs. placebo

CVD or stroke events, Grade 3 or 4 retinopathy, doubling of creatinine or BUN

Increase in reduced eGFR in the non-CKD group and AKI/ARF overall was observed in the intensive group. While of uncertain etiology and significance, there is speculation this could be an acute hemodynamic effect, especially given the findings regarding albuminuria.

Limitations: Few participants were untreated at baseline ~9%, so SPRINT provides little if any insight at present regarding BP-lowering medication initiation for untreated people with SBP 130–139.

**Size:** 6,083 pts

**Exclusion criteria:** Life-threatening illness, contraindication to an ACEI or diuretic, a plasma creatinine concentration of more than 2.5 mg per deciliter (221 micromol per liter), malignant hypertension, or dementia

**Note:** Clinicians chose which ACE or diuretic

---

### Fletcher A, et al., 1988 (279) 2907053

**Aim:** Monitoring event rates in pts assigned to treatment by clinicians

**Study type:** Observational

**Size:** 2,607

**Inclusion criteria:** Age >18 y

**Exclusion criteria:** N/A

**Intervention:** N/A

**1° endpoint:** Total mortality incident “IHD”

**Safety endpoint:** N/A

**Summary:** BBs reduced mortality in men but not women (p<0.01)

---

### Forette F, et al., 2002 (280) 12374512

**Aim:** Legacy follow-up for dementia prevention

**Study type:** RCT with legacy follow-up

**Size:** 2,902 in the legacy follow-up

**Inclusion criteria:** Age ≥60 y

**Exclusion criteria:** HTN 2° to a disorder that needed specific medical or surgical treatment; congestive HF; dissecting aortic aneurysm; serum creatinine concentration at presentation of 180 micromol/l or more; stroke or MI in the y before the study; dementia; substance abuse; any disorder prohibiting a sitting or standing position; any severe concomitant or non-CVD

**Intervention:** Nitrendipine + HCTZ

**Comparator:** Placebo

**1° endpoint:** Incidence of dementia

**2° endpoint:** Cognitive decline measured by MMSE

**Safety endpoint:** N/A

- Cases Active: 21
- Cases Placebo; 43
- Rate 3.3 vs. 7.4 cases/1,000 pt y 0.38 (95% CI: 0.23–0.64; p<0.001)
- MMSE: No impact

**Summary dementia:**

- Study discontinued early for CVD benefit so a legacy follow-up with both groups (off protocol) yielded a follow-up of 3.7 y SBP was 149 mm Hg in treatment vs. 156 mm Hg in control arm

**Summary:**

- Compared with the controls, long-term antihypertensive therapy reduced the risk of dementia by 55%, from 7.4–3.3 cases per 1,000 pt-y (43 vs. 21 cases; p<0.001). After adjustment for sex, age, education, and entry BP, the relative HR associated with the use of nitrendipine was 0.38 (95% CI: 0.23, 0.64), p<0.001.
- Lack of impact on MMSE not surprising given low sensitivity to change and large sample size

<td><strong>Aim:</strong> Compare ability of IV nicardipine and labetalol to lower BP in acute hemorrhagic or ischemic stroke.</td>
</tr>
<tr>
<td><strong>Study type:</strong> RCT (pseudo-randomization)</td>
</tr>
<tr>
<td><strong>Inclusion criteria:</strong> Pts with acute hemorrhagic or ischemic stroke who were at or exceeded AHA guidelines BP recommendations.</td>
</tr>
<tr>
<td><strong>Exclusion criteria:</strong> Traumatic brain injury; intracranial neoplasm, received antihypertensive medication within previous 24 h, brain stem herniation, immediate brain death, acute MI, or bradycardia &lt;50 bpm.</td>
</tr>
<tr>
<td><strong>Results:</strong> All pts receiving nicardipine achieved BP goal Compared with 61% in the labetalol group (p=0.001). 89% of the nicardipine group achieved goal within 60 min vs. 25% in the labetalol group (p&lt;0.001). The nicardipine group had better maintenance of BP, greater percent of time spent within goal and less BP variability compared with the labetalol group (p&lt;0.001). Less rescue medication had to be given to the nicardipine than the labetalol group (p&lt;0.001).</td>
</tr>
<tr>
<td><strong>Conclusions:</strong> Pts treated with nicardipine are more likely to reach the physician-specified TR than those treated with labetalol. In this study (2014), initial SBP was not a predictor of the ability to achieve the pre-specified TR in 30 min. Subgroup analysis demonstrated the similar results for sub-populations with end-organ damage (n=141) and renal dysfunction (n=104).</td>
</tr>
</tbody>
</table>

**Limitations:** Very small; pseudo-randomization. **Limitations:** Study excluded pts with BP ≥220/120 mm Hg, so the results do not apply to such pts. Pts treated acutely with thrombolytic therapy were excluded. Trial performed exclusively in Chinese pts.
| Study type: RCT | Study type: RCT | Results: 719 of 1,382 pts receiving intensive treatment as compared to 765 of 1,412 pts receiving guideline-recommended treatment had a 1° outcome event [OR with intensive treatment: 0.87; 95% CI: 0.75–1.01; p=0.06]. Ordinal analysis showed significantly lower modified Rankin scores with intensive treatment (OR for greater disability: 0.87; 95% CI: 0.77–1.00; p=0.04). Mortality was 11.9% in the group receiving intensive treatment and 12.0% in the group receiving guideline-recommended treatment. Nonfatal serious events were not significantly different between the groups. | Limitations: No major limitations. | Conclusions: In pts with ICH, intensive lowering of BP resulted in a borderline significant reduction in the rate of death or severe disability at 90 d. An ordinal analysis of modified Rankin scores indicated improved functional outcomes with intensive lowering of BP. Intensive BP reduction was shown to be safe and to result in significantly better health-related quality of life. |
| INTERAC-2 | Anderson CS, et al., 2013 (191) | To compare the management strategy of targeting SBP<140 mm Hg within 1 h with the current guideline strategy of targeting SBP to <180 mm Hg with the use of agents of the physicians' choosing. | This was an international, multicenter, prospective randomized open-treatment, blinded endpoint trial. 719 of 1,382 pts receiving intensive treatment as compared to 765 of 1,412 pts receiving guideline-recommended treatment had a 1° outcome event [OR with intensive treatment: 0.87; 95% CI: 0.75–1.01; p=0.06]. Ordinal analysis showed significantly lower modified Rankin scores with intensive treatment (OR for greater disability: 0.87; 95% CI: 0.77–1.00; p=0.04). Mortality was 11.9% in the group receiving intensive treatment and 12.0% in the group receiving guideline-recommended treatment. Nonfatal serious events were not significantly different between the groups. | Limitations: No major limitations. | Conclusions: In pts with ICH, intensive lowering of BP resulted in a borderline significant reduction in the rate of death or severe disability at 90 d. An ordinal analysis of modified Rankin scores indicated improved functional outcomes with intensive lowering of BP. Intensive BP reduction was shown to be safe and to result in significantly better health-related quality of life. |

**Aim:** To determine the efficacy and safety of clevidipine vs. standard-of-care (SOC) iv antihypertensive therapy in hypertensive acute HF.

**Results:** More clevidipine pts reached target BP reduction (71%) than did those receiving standard-of-care (37%) and clevidipine was faster to target (p=0.0006). Serious adverse events were similar between clevidipine and standard-of-care.

**Limitations:** Small study, open-label design.

**Conclusions:** In hypertensive acute HF, clevidipine safely and rapidly reduced BP and improved dyspnea more effectively that standard-of-care.

### Farias S, et al., 2014 13849948 (287)

**Aim:** To determine if achievement of target BP is less likely in pts with higher initial BP using a post hoc analysis in a pt subset from CLUE

**Inclusion criteria:** SBP ≥180 mm Hg on 2 consecutive occasions 10 min apart in the ED.

**Exclusion criteria:** Contraindication to giving either a BB or CCB or clinical scenarios in which a compelling agent was indicated.

**Results:** Early achievement of target SBP was independent of presenting SBP.

**Limitations:** 2º analysis of the 1º CLUE study; SBP control only evaluated for the first 30 min posttreatment; no inclusion of critically ill pts; 80% of enrolled subjects were African-American.

**Conclusions:** Presenting SBP does not appear to affect the ultimate ability to reduce BP for pts with marked, acute HTN in the ED when treated with either IV nicardipine or IV labetalol.

<tr>
<th>Study</th>
<th>Treatment vs. Placebo</th>
<th>Exclusion criteria: History and/or signs of major CVDs (e.g., previous MI, coronary artery surgery, major arrhythmias, conduction defect, recent stroke, carotid artery disease, ≥2 TIA and signs or symptoms in a single neurological distribution); other major diseases (e.g., cancer, alcoholic liver disease, established renal dysfunction) with competing risk factors for the 1° endpoint; stroke; presence of medical management problems (e.g., insulin dependent DM, history of dementia, evidence of alcohol abuse); bradycardia; people maintained on BBs, diuretics, other antihypertensive drugs, anticoagulants.</th>
<th>Comparator: Placebo</th>
<th>SBP Treatment/Placebo difference: -12 mm Hg Achieved mean SPB: 143 mm Hg in treatment group vs. 155 mm Hg in placebo group</th>
<th>Cases: • Active: 37 • Placebo: 44 • p=0.84 (0.54,1.31) • No cognitive function instrument included in trial</th>
<th>Summary: Nonsignificant 16% lower incidence of incident instrumental activity of daily living disability. However, assignment to the placebo group and the resulting occurrence of CV events independently predicted missed assessments. However, when 20%–30% and 40%–80% of the subjects who missed the assessment were assumed to be cognitively/functionally impaired, assignment to active treatment reduced the risk of these outcomes. Thus, in the SHEP study, the cognitive and functional evaluations were biased toward the null effect by differential dropout. This might have obscured the appraisal of a protective effect of treatment on the cognitive and functional decline of older hypertensive adults</th>

</table>
### Exclusion criteria:
N/A

### Results:
**1° endpoint:** Intraoperative and postoperative upper airway complications, in-hospital complications, and 30-d mortality

**Results:** ACEI usage was not associated with either 30-d mortality (OR: 0.93; 95% CI: 0.73–1.19; p=0.22)

- No association found between use of ACEIs and intraoperative or postoperative upper airway complications, in-hospital complications, or 30-d mortality

### Study type: Matched observational study
**Size:** 79,228 pts

### Inclusion criteria:
Pts with noncardiac surgery

### Exclusion criteria:
N/A

**1° endpoint:** Hypotension requiring vasopressors at or shortly after induction of anesthesia

**Results:** Pts receiving preoperative ACEI or ARA were more likely to develop hypotension requiring vasopressors at or shortly after induction of anesthesia. Sufficient data were not present to assess other outcomes.

- Pts receiving immediate preoperative ACEI or ARA were more likely to develop hypotension requiring vasopressors at or shortly after induction of anesthesia. Sufficient data were not present to assess other outcomes.

### Study type: Review of observational and randomized studies
**Size:** 434 pts

### Inclusion criteria:
Adult pts, most >18 y, nonemergent surgery, using ACEI or ARA chronically

### Exclusion criteria:
N/A

**1° endpoint:** 30-d all-cause death, stroke, or myocardial injury

**Results:** ACEI/ARB users who withheld ACEI/ARB in the 24 H before surgery were less likely to suffer death, MI or stroke 0.82; 95% CI: 0.70–0.96; p=0.01

- Withholding ACEI/ARB before major noncardiac surgery was associated with a lower risk of death and postoperative vascular events.

</table>
| Schroeder K, et al., 2004 (307) 15078641 | **Study type:** Systematic review of RCTs. **Size:** 38 studies testing 58 different interventions containing data on 15,519 pts; 9 studies assessed simplification of dosing regimen | **Inclusion criteria:**
  - Database search for all RCTs, all languages, in Cochrane Controlled Trials Register, MEDLINE, EMBASE, and CINAHL (all y through 2002)
  - Population of interest were pts with essential HTN in primary care, outpatient, or community setting
  - Interventions aimed to increase adherence to BP-lowering medication
  - Reported outcome was adherence | **1° endpoints:** Adherence as assessed by pill counts, self-report, or electronic monitoring system |

**Results:**
- 9 studies assessed simplification of dosing regimen, 7 of which compared adherence associated with frequency of administration (twice daily vs. once daily [n=6] or 3 times daily vs. twice daily [n=1]).
- All studies examining effect of dosing frequency demonstrated improved adherence (range: 8%, 19.6% improvement; p<0.01 for all).

- Adherence to antihypertensive medication was significantly improved with once daily vs. multiple daily dosing regimens. Most studies used an electronic monitoring system. Limitations in the systematic review include heterogeneity in pts, interventions, and outcomes, and the majority of studies were of low quality. In addition, different definitions of adherence in the RCTs make it difficult to examine the precise relationship of adherence to BP control.

<tbody>
<tr>
<td>Iskedjian M, et al., 2002 (308) 11911560</td>
<td>Meta-analysis</td>
<td>8 studies involving a total of 11,485 observations (1,830 for once daily dosing, 4,405 for twice daily dosing, 4,147 for &gt;twice daily dosing, 9,655 for maximum daily dose).</td>
<td>• Database search of MEDLINE, EMBASE, and International Pharmaceutical Abstracts (1980–1998) • 1° studies that compared adherence rates between different dosing regimens • Prospective trials (e.g., RCTs, cohort studies), retrospective studies, database analyses • Any published study using an instrument to measure adherence, but must have used some measurement tool in each comparison group. • Adherence rates to solid, oral dosage form for treatment of HTN of at least 10 wk duration</td>
<td>Medication adherence rates compared between once daily and maximum daily dose, once daily and twice daily, twice daily and &gt;twice daily</td>
<td>• Average adherence rates with once daily dosing were greater compared to maximum daily dose regimens (91.4% [SD=2.2%] vs. 83.2% [SD=3.5%]; z=4.46; p&lt;0.001.) • Average adherence rates with once daily dosing were greater compared to twice daily dosing regimens (92.7% [SD=2.3%] vs. 87.1% [SD=2.9%]; z=2.22; p=0.026.) • There was no difference in adherence rates between regimens dosed twice daily or greater than twice daily (90.8% [SD=4.7%] vs. 86.3% [SD=6.7%]; z=1.82; p=0.069).</td>
<td>• Antihypertensive regimens dosed once daily were associated with significantly improved adherence compared to twice daily or maximum daily dose regimens.</td>
</tr>
<tr>
<td>Claxton AJ, et al., 2001 (309) 11558866</td>
<td>Systematic review</td>
<td>76 studies</td>
<td>• Database search of MEDLINE, Psychinfo, HealthStar, Health &amp; Psychological Instruments, and Cochrane library 1986–2000 • Compliance rates assessed using electronic monitoring device • Data pooled to calculate mean compliance with once daily, twice daily, 3 times daily, and 4 times daily dosing regimens</td>
<td>Mean compliance rates by prescribed dose regimen</td>
<td>• 26 studies evaluated CVD; 17 HTN only. • For all studies, mean dose-taking compliance defined as number of appropriate doses taken during each day was 79% for once daily, 69% for twice daily, 65% for 3 times daily and 51% for 4 times daily dosing (p≤0.001 for once daily vs. 3 times daily, once daily vs. 4 times daily, and twice daily vs. 4 times daily; no statistically significant between once daily vs. twice daily or twice daily vs. 3 times daily dosing).</td>
<td>• Medication compliance as measured by electronic monitoring devices were improved with less frequent dosing. Once-daily dosing was associated with the greatest rate of compliance. Limitations of this analysis include heterogeneity of studies and disease states studied.</td>
</tr>
</tbody>
</table>
• For 14 studies that assessed ability to take doses within prescribed time frame, once daily regimens were associated with better dose-time compliance (74% ± 31%) compared to twice daily (58% ± 23%) or 3 times daily (46% ± 8%); formal statistical analysis not conducted due to too few studies.

| Sherrill B, et al., 2011 (310) 22142349 | Study type: Meta-analysis to compare health resource use cost, adherence, and persistence between groups of pts taking antihypertensives as SPCs vs. free-equivalent components.  
Size: 15 retrospective database studies in HTN | Inclusion criteria:  
• Database search of PubMed, EMBASE, The Cochrane Library, and EconLit (no limit on publication dates)  
• English-language publications  
• Clinical trial or observational study (e.g., database or registry) that compared SPC with free-equivalent components  
• Data on compliance, adherence, persistence, and/or health care costs and/or resource use (unadjusted cost analyses)  
1° endpoints: Health care costs, adherence, persistence  
Results:  
• All-cause total costs were estimated to be lower with SPC vs. free-equivalent components free-equivalent components by $2,039 (95% CI: $1030, $3047) in 2009 dollars and HTN/CV-related costs were lower by $709 (95% CI: $117, $1,032), 2009 dollars.  
• Adherence as measured by MPR was greater for SPC vs. free-equivalent components (total inverse variance 13.31; 95% CI: 8.26–18.35).  
• Persistence to therapy was greater with SPC than free-equivalent components (risk ratio: 2.13; 95% CI: 1.11–4.09)  
• Medication adherence and persistence was significantly greater with SPC than free-equivalent components. Costs were also significantly lower with SPC than with free-equivalent components. However, cost data should be interpreted with caution considering unadjusted costs were used in this meta-analysis. In addition, heterogeneity was present in analyses of each outcome. This meta-analysis did not include the observational study by Yang et al. as that study used an adjusted analysis methodology. |
| Yang W, et al., 2010 (311) 20629600 | Study type: Observational analysis using multivariate regression-adjusted analysis to compare compliance/persistence, health care resources, and cost associated with SPC or FC antihypertensives over 6 mo study period both nationally and at the state level.  
Size: 579,581 pts (382,476 SPC and 197,375 FC) identified in MarketScan Database (2006–2008) | Inclusion criteria:  
• Pts in MarketScan Database  
• Diagnosis of HTN based on ICD-9 codes 401.xx and 405.xx  
• Pts initiated on any of the following SPC treatments or the same FC: ARB + CCB, ARB + HCTZ, ACEI + HCTZ  
• For SPC cohort, at least 1 prescription filled in observational window  
• For FC cohort, pts filled individual components separately within 15 d of each other and with 15 d overlap of supply  
• ≥18 y  
Endpoints:  
• 1° outcome: Compliance and persistence with the index therapy (SPC or FC) measured by MPR within 6 mo of index date  
• 2° outcomes: Healthcare resource utilization (number of all-cause hospitalizations, number ER visits, number CV hospitalizations, and CV-related ER visits) and health care costs (all cause medical costs, all-prescription drug costs, CV-related medical service costs, and HTN prescription-related drug costs)  
Results:  
• Compliance nationally as assessed by MPR was improved in pts taking SPC vs. FC antihypertensives (difference=11.6%; 95% CI: 11.4%–11.7%).  
• This large observational study found that medication compliance/persistence to antihypertensives was improved with SPC compared to FC using an adjusted multivariate regression model. All-cause medical costs were also decreased with the use of SPC antihypertensives, although prescription costs were greater. |
### Gupta, et al., 2010 (312)

**Study type:** Meta-analysis to assess compliance, adherence, persistence, BP control, and safety with FDC antihypertensives compared to their free components

**Size:** 15 studies (n=32,331) with ≥1 evaluated outcome; 3 cohort studies and 2 trials of compliance (n=17,999); 3 cohort studies on persistence (n=12,653); 5 trials of adverse drug effects of FDCs (n=1,775); 9 trials of BP change (n=1,671)

**Inclusion criteria:**
- Database search of PubMed (1966–February 2008), Web of Science (1970 to April 2008), and the Cochrane Controlled Trial (1800–April 2008).
- Clinical trials or cohort studies included if published in English and compared an FDC of hypertensive agents with free-drug combination of its components.
- Extractable data reported including compliance (or adherence), persistence, BP-lowering effects, adverse effects

**1st endpoint:**
- Compliance (or adherence) and persistence to therapy
- BP-lowering efficacy
- Adverse effects

**Results:**
- Use of FDC therapy was associated with a 21% increase in compliance, both in the cohort studies (n=5) and clinical trials (OR: 1.21; 95% CI: 1.00–1.47) and (OR: 1.21; 95% CI: 1.03–1.43). There was a 50% increase in persistence with therapy, but this was not statistically significant (OR: 1.54; 95% CI: 0.95–2.49).
- Analysis of all 6 retrospective cohort studies indicated that FDC therapy was associated with a 29% increase in compliance and persistence to therapy (OR: 1.29; 95% CI: 1.11–1.50). No sign of heterogeneity of publication bias.
- FDC therapy was associated with a nonsignificant reduction in SBP (-4.1 mm Hg; 95% CI: -9.8–1.5 mm Hg; p=0.15) and DBP (-3.1 mm Hg; 95% CI: -7.1–0.9 mm Hg; p=0.13) compared to free-drug combinations. Strong evidence of heterogeneity but no evidence of publication bias.
- FDC therapy was associated with a 20% nonsignificant decrease in adverse effects (OR: 0.80; 95% CI: 0.60–1.08).

**Continuous eligibility in database for 6 mo after index date**
- Valid 3-digit zip code in database

- Treatment discontinuation rates were lower with SPC vs. FC antihypertensives (40.7% vs. 59.3%; 95% CI: 0.46–0.48).
- There were fewer all-cause hospitalizations and ER visits in SPC vs. FC pts IRR: 0.77 (95% CI: 0.75–0.79) and IRR: 0.87 (95% CI: 0.86, 0.89), respectively.
- All-cause medical costs were reduced with SPC vs. FC (-$208; 95% CI: -$302– -$114), but antihypertensive prescription costs were greater ($53; 95% CI: $51–$55).
### Bangalore S, et al., 2007 (313) 17679131

**Study type:** Meta-analysis to assess if compliance is improved with FDC therapy compared to free-drug regimens in chronic diseases including HTN, HIV, tuberculosis, and DM

**Size:** 9 studies total (n=20,242), 4 of which were in hypertensive populations (n=17,175)

**Inclusion criteria:**
- Database search of MEDLINE (1966–2005)
- Studies included if published in English and compared an FDC with free-drug combination of its components and reported medication compliance (adherence) or persistence

**1° endpoint:** Compliance, considered as either adherence or persistence to medication therapy

**Results:**
- Use of FDC therapy was associated with a 26% decreased risk of noncompliance vs. free-drug combinations (pooled RR: 0.74 (95% CI: 0.69, 0.80), p<0.0001) in all diseases states.
- There was no evidence of heterogeneity.
- In hypertensive pts, FDC was associated with 24% decreased risk of noncompliance (pooled RR: 0.76 (95% CI: 0.71, 0.81), p<0.0001) compared to free-drug regimen. There was no evidence of publication bias.
- Marked heterogeneity in how compliance was measured among studies

### Kumagai N, et al., 2013 (314) 23072348

**Study type:** Prospective, multicenter, observational study of pts converted from free-drug combinations of an ARB and amlodipine to the same product as a FDC.

**Size:** 196 pts

**Inclusion criteria:**
- Outpatients with essential HTN
- Self-measured home BP
- Prescribed FDC of an ARB (8 mg candesartan, 80 mg valsartan, or 40 mg telmisartan) and 5 mg and 5 mg amlodipine
- Pts divided into 2 groups: Group 1 received an ARB and amlodipine in the morning as free drug combinations and Group 2 took ARB in the morning and amlodipine in the evening. After 1 mo, both groups converted to once daily FDC product.

**Exclusion criteria:**
- Severe renal or liver dysfunction
- Severe HF
- Prescription of time-specific packs

**Endpoints:**
- Adherence to antihypertensive therapy as measured by self-reporting
- Self-monitored BP measurements and clinical BP measurements before and after switch to FDC antihypertensive therapy.
- Drug costs

**Results:**
- Self-monitoring BP measurements taken during early morning was lower with FDC compared to free-drug combinations (-5 mm Hg SBP, -2 mm Hg DBP; p<0.01 for both)
- Average clinic BP was lower with FDC compared to free-drug combination (-5 mm Hg SBP, -2 mm Hg SBP; p<-0.01).
- Self-reported adherence was improved with FDC vs. free-combination agents (~99% vs. 95% p<0.01). SBP was significantly lower in the group with improved adherence (~7.5 mm Hg)

- Use of FDC with an ARB and amlodipine was associated with improved adherence, lower BP, and decreased health care costs compared to free-drug combination therapy. Limitations to this study include the observational design, low numbers of pts, use of self-reported adherence, short follow-up period, non-U.S. country with a different health care system (Japan), and very high baseline rate of adherence (~95%) as well post-switch to FDC (~99%), which is not what is seen in usual practice.

<td>Newly diagnosed and treated hypertensive pts ≥35 y initially free of CVD identified from Italian general pt registry.</td>
<td></td>
</tr>
<tr>
<td>Exclusion criteria:</td>
<td>CHD, cerebrovascular disorders, congestive HF who had been hospitalized for CABG or coronary angioplasty, those recovered in a cardiology ward before index diagnosis, incident CV event in the 180 d after index diagnosis, pts receiving nitrates</td>
<td></td>
</tr>
<tr>
<td>1° endpoint:</td>
<td>Describe adherence to antihypertensive therapy and its associate with concurrent drug use, comorbidities, and CV risk factors. Adherence was estimated by calculating the proportion of days which pt had pills available during the follow-up.</td>
<td></td>
</tr>
<tr>
<td>Results:</td>
<td>At baseline (6 mo after index diagnosis), adherence rates were high (≥80% proportion of days covered) in 8.1% of pts, intermediate (40-79% proportion of d covered) in 4.5%, and low (≤40% proportion of d covered) in 51%. Multiple drug treatment (1.62; 95% CI: 1.43–1.83), dyslipidemia (1.52; 95% CI: 1.24–1.87), DM (1.40; 95% CI: 1.15–1.71), obesity (1.50; 95% CI: 1.26–1.78) and antihypertensive combination therapy (1.29; 95% CI: 1.15–1.45) were associated with high adherence to treatment (p&lt;0.001).</td>
<td></td>
</tr>
</tbody>
</table>

- High adherence was associated with a 38% decreased risk of CV events compared with low adherence. Combination therapy associated with 29% improved adherence compared to monotherapy.

- Older age was associated with improved MPR (75.2% for those ≥64 y. vs. 69.6% for 18 to <36 y; p=0.023).
**Exclusion criteria:** Pts who received <2 prescription fills, did not continuously have prescriptions refilled for each medication, or switched from 1 medication to another without a time overlap.

**Dickson M, et al., 2008 (317)**

**Study type:** Retrospective cohort study

**Size:** 5,704 pts

**Inclusion criteria:**
- 65–100 y on index date
- Received at least 2 prescriptions for study drugs (amlodipine/benazepril FDC n=2336] or DHP-CCB and ACEI as separate agents [n=3368] between 1997–2001
- Continuously eligible for Medicaid for 12 mo following index date

**Exclusion criteria:**
- >180 d of hospitalization
- <30 d of study drug supply
- Any nursing home claims during the 12 mo follow-up period

**1º endpoint:** Determine rates of compliance (MPR) and total costs of care (defined as sum of payments for Medicaid claims for ambulatory care, hospital claims, prescription drug claims, and Medicare ross claims) in pts treated with FDC amloidipine/benazepril vs. a DHP-CCB and ACEI prescribed as free-combination agents.

**Results:** MPR was significantly higher for pts receiving FDC compared with free-combination therapy (63.5% vs. 49%; p<0.05). Average total cost of care (2002 value) was $3,179 with FDC compared to $5,236 with free-combination agents (p<0.0001). Multivariate regression analysis indicated an increase of 0.5% for each 1-unit increase in MPR, and for each comorbidity there was a 10.4% increase. Total cost of care for FDC group was 12.5% lower than free-combination group (p<0.003)

**FDC combination therapy with amloidipine/benazepril was associated with better compliance than a DHP-CCB and ACEI as free-combination agents. FDC was also associated with lower total costs of care.**

### Carter BL, et al., 2009 (321) 19858431

**Aim:** Determine potency of interventions for BP involving nurses and pharmacists

**Study type:** Meta-analysis

**Size:** 37 RCTs of team-based HTN care involving nurse or pharmacist intervention

**Inclusion criteria:** RCT of team-based HTN care involving nurse or pharmacist intervention

**Exclusion criteria:** Absence of above

**Intervention:** Team-based HTN care involving nurse or pharmacist intervention in nearly all studies involving nurses or pharmacists in clinics, consistent and dedicated case management activities were provided that were distinct from traditional nursing or pharmacist duties. However, pharmacists in community pharmacies usually had to incorporate the intervention with traditional medication dispensing functions.

**Comparator:** Usual care

**1° endpoint:** OR (95% CI) for controlled BP were nurses: 1.69 (1.48, 1.93); pharmacists within primary care clinics: 2.17 (1.75, 2.68); and community pharmacists: 2.89 (1.83, 4.55). Mean (SD) reductions in SBP were: nurse intervention, 5.84 (8.05) mm Hg; pharmacists in clinics, 7.76 (7.81) mm Hg; and community pharmacists, 9.31 (5.00) mm Hg. There were no significant differences between nurse and pharmacist effects (p≥0.19).

**Safety endpoint:** N/A

**Summary:** Interventions involving pharmacists or nurses were associated with significantly improved BP control.

### Clark CE, et al., 2010 (322) 20732968

**Aim:** Review trials of nurse led interventions for HTN in primary care to clarify the evidence base, establish whether nurse prescribing is an important intervention

**Inclusion criteria:** RCT of nursing intervention for HTN

**Exclusion criteria:** Absence of above

**Intervention:** Interventions were categorized as nurse support delivered by either telephone, community monitoring or nurse led clinics. These were held in either primary care or 2° care. 1 study used alternate

**1° endpoint:** Compared with usual care, interventions that included a stepped treatment algorithm showed greater reductions in SBP (weighted MD -8.2 mm Hg (95% CI: -11.5—-4.9); nurse performed the intervention (-4.03 mm Hg; p=0.04), or nurse performed the intervention (-3.94 mm Hg; p=0.04).

**Safety endpoint:** N/A

**Summary:** Nurse led interventions that included a stepped treatment algorithm or nurse led prescribing showed significantly greater reductions of SBP and DBP than usual care. Telephone monitoring was associated with higher achievement of study targets for BP. Community monitoring showed lower

</tr>
</tbody>
</table>

sessions with nurses at home and in general practice. 14 studies included a stepped treatment algorithm and 9 included nurse prescribing in the protocol.

**Comparator:** Usual care

- Nurse prescribing showed greater reductions SBP, $-8.9$ mm Hg, (95% CI: $-12.5$ to $-5.3$), and DBP, $-4.0$ mm Hg, (95% CI: $-5.3$ to $-2.7$);
- Telephone monitoring showed higher achievement of BP targets (RR: 1.24; 95% CI: 1.08 to 1.43);
- Community monitoring showed greater reductions in (weighted MD) SBP, $-4.8$ mm Hg, (95% CI: $-7.0$ to $-2.7$), and DBP, $-3.5$ mm Hg, (95% CI: $-4.5$ to $-2.5$).

**Safety endpoint:** N/A

<table>
<thead>
<tr>
<th>Proia KK, et al., 2014 (323) 24933494</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Aim:</strong> Examine current evidence on the effectiveness of team-based care in improving BP outcomes (update of prior systematic review)</td>
</tr>
<tr>
<td><strong>Study type:</strong> Systematic review</td>
</tr>
<tr>
<td><strong>Size:</strong> 52 studies of team-based primary care for pts with 1° HTN</td>
</tr>
</tbody>
</table>

**Inclusion criteria:** Study of team-based care; conducted in a high-income economy; reported at least 1 BP outcome of interest; included a comparison group or had an interrupted time-series design with at least 2 measurements before and after the intervention; targeted populations with 1° HTN or populations with comorbid conditions such as DM as long as the 1° focus of the intervention was BP control; and did not

**Intervention:** Team-based care was defined as adding new staff or changing the roles of existing staff to work with a PCP for HTN care. Team members who collaborated with pts and PCPs were predominantly nurses (28 studies); pharmacists (15 studies); both nurses and pharmacists (5 studies); or community health workers, integrated care managers, or behavioral interventionists (4 studies). Key roles included HTN medication management, active pt follow-up, and adherence and self-management support. Interventions were usually

**1° endpoint:**
- Proportion with controlled BP: Absolute percentage point (pct pt) change in pts with controlled BP from 33 studies comparing team-based care to usual care: median effect estimate was 12 pct pts (IQI=3.2 to 20.8 pct pts). Most individual effect estimates in the favorable direction were significant ($p<0.05$).
- Reduction in SBP (44 studies): The median reduction in SBP was 5.4 mm Hg (IQI=2.0 to 7.2 mm Hg). Most individual effect estimates were significant ($p<0.05$).
- Reduction in DBP: The overall median reduction in

**2° endpoints:** Compared with pts in usual care, the proportion of pts receiving team-based care with “high” medication adherence (defined as taking medications as prescribed >80% of the time) increased by a median of 16.3 pct pts (9 studies).

**Stratified analyses for BP outcomes:**
- Team member role in medication management: Larger improvements in BP outcomes than overall estimates were demonstrated when team members could make changes to medications independent of the PCP or team members could provide medication recommendations and make changes with the PCP’s approval as compared to team members providing only adherence support and information on medication and HTN.
Exclusion criteria: Inclusion of populations with 2\textsuperscript{o} HTN (e.g., pregnancy) or with a history of CVD (e.g., MI).

Comparator: Usual care

Intervention: Pharmacist intervention delivered by a pharmacist alone or in collaboration with other healthcare professionals. Pharmacist interventions mainly included pt education, feedback to physician, and medication management.

DBP was 1.8 mm Hg (IQI=0.7–3.2 mm Hg) from 38 studies.

Safety endpoint: No harm to pts was identified from team-based care interventions in the included studies or the broader literature.

Safety endpoint: N/A

1\textsuperscript{o} endpoint: Pharmacist interventions were associated with a large reduction in systolic and DBP of -7.6 mm Hg (95% CI: -9.0–-6.3 mm Hg) and -3.9 mm Hg (95% CI: -5.5–-2.8 mm Hg), respectively

Summary: Pharmacist interventions, alone or in collaboration with other healthcare professionals, improved BP management.

Limitations:

- Included studies reported significant differences in pt demographics between intervention and comparison groups at baseline, possible contamination within intervention and comparison groups, and issues related to inadequate description of populations and implemented interventions.

Aim: Assess effect of pharmacists interventions on BP and determine potential determinants of heterogeneity

Study type: Meta-analysis

Size: 39 RCTs were included with 14,224 pts

Inclusion criteria: RCT of pharmacist intervention delivered by a pharmacist alone or in collaboration with other healthcare professionals

Exclusion criteria: Absence of above

Santschi V, et al., 2014 (324) 24721801
| **Shaw RJ, et al., 2014 (325) 25023250** | **Aim:** Determine whether nurse-managed protocols are effective for outpatient management of pts with DM, HTN, and hyperlipidemia (HTN RCT outcomes only included here)  
**Study type:** Meta-analysis  
**Size:** 12 RCTs, with 10,362 pts, of nurse-managed protocols for outpatient management of HTN  
**Inclusion criteria:** RCT of nurse-managed protocols for outpatient management of HTN  
**Exclusion criteria:** Absence of above  
**Intervention:** Involvement of a registered nurse or a licensed practical nurse functioning beyond the usual scope of practice, such as adjusting medications and conducting interventions based on a written protocol. All studies used a nurse who titrated medications by following a protocol.  
**Comparator:** Usual care  
**1° endpoint:**  
- SBP and DBP decreased by 3.68 mm Hg (95% CI: 1.05–6.31 mm Hg) and 1.56 mm Hg (95% CI: 0.36–2.76 mm Hg), respectively, with high variability (I²>70%)  
- Nurse-managed protocols were more likely to achieve target BP than control protocols (OR: 1.41; 95% CI: 0.98–2.02), though difference was not significant and treatment effects were highly variable (Q 35.20; I²=74%).  
**Safety endpoint:** N/A  
**Summary:** Nurse-managed protocols for HTN care were associated with a mean decrease in SBP and DBP but not increase in HTN control. |
| **Carter BL, et al., 2015 (326) 25805647** | **Aim:** Evaluate if a physician/pharmacist collaborative model would be implemented as determined by improved BP control and whether long-term BP control could be sustained  
**Study type:** Cluster RCT  
**Size:** 32 primary care offices from 15 states enrolled 625 pts with uncontrolled HTN; 54% from racial/ethnic minority groups and 50% with DM or CKD  
**Inclusion criteria:** Offices were required to have an onsite clinical pharmacist must have practiced in the office. Pts were eligible if they were English or Spanish speaking, ≥18 y with uncontrolled BP as measured by the SC on the baseline visit.  
**Exclusion criteria:** Absence of above  
**Intervention:** Pharmacist conducted medical record review and a structured interview with the subject, including 1) a medication history; 2) an assessment of knowledge of BP medications, dosages and timing, and potential side effects; and 3) other barriers to BP control (e.g., side effects and nonadherence). The model recommended a telephone call at 2 wk, structured face-to-face visits at baseline, 1, 2, 4, 6, and 8 mo and additional visits if BP remained uncontrolled. The pharmacist created a care plan with recommendations for the physician to adjust  
**Comparator:** Usual care  
**1° endpoint:**  
- BP control at 9 mo was 43% in intervention offices compared with 34% in control group (adjusted OR: 1.57 (95% CI: 0.99, 2.50), p=0.059).  
**Safety endpoint:** N/A  
**2° endpoints:**  
- The adjusted difference in mean SBP/DBP between the intervention and control groups for all pts at 9 mo was −6.1/−2.9 mm Hg (p=0.002 / p=0.005, respectively), and it was −6.4/−2.9 mm Hg (p=0.009 / p=0.044, respectively) in pts from racial or ethnic minorities.  
- BP control and mean BP were significantly improved in pts from racial minorities in intervention offices at 18 and 24 mo (p=0.048 and p<0.001) compared with the control group.  
**Summary:** Although the results of the 1° outcome (BP control) were negative, the key 2° endpoint (mean BP) was significantly improved in the intervention group. Thus, the findings for 2° endpoints suggest that team-based care using clinical pharmacists significantly
therapy based on the JNC-7, and the BP goals were <140/90 mm Hg for uncomplicated HTN or <130/80 mm Hg for pts with DM or CKD. The pharmacists did not follow algorithms or protocols other than JNC-7. Physicians were free to accept or to reject any recommendation or to modify the plan. Recommendations to pts focused on medication education, improving adherence, and strategies to implement lifestyle modifications.

**Comparator:** Pharmacists in control offices were instructed to avoid intervention for study pts with HTN, but they could provide usual care curbside consultations if physicians specifically asked questions.

</tbody>
</table>
context of an established QI initiative.

**Study type and size:**
A cluster-randomized trial of small (<10 clinicians) primary care clinics in New York City from April 2009 through March 2010.

A mean of 4,592 (median, 2,500) pts at the intervention group clinics and 3,042 (median, 2,000) at the control group clinics.

and pt registry functionalities and QI specialists offering technical assistance.

- Incentivized clinics were paid for each pt whose care met the performance criteria, but they received higher payments for pts with comorbidities, who had Medicaid insurance, or who were uninsured (maximum payments: $200/pt; $100,000/clinic).

Quality reports were given quarterly to both the intervention and control groups.

6.1%, difference: 6.0% (95% CI: 2.2%, 9.7%), p<0.001 for interaction term), BP control (no comorbidities: 9.7% vs. 4.3%, difference: 5.5% (95% CI: 1.6%, 9.3%), p=0.01 for interaction term; with DM: 9.0% vs. 1.2%, difference: 7.8% (95% CI: 3.2%, 12.4%), p=0.007 for interaction term; with DM or ischemic vascular disease: 9.5% vs. 1.7%, difference: 7.8% (95% CI: 3.0%, 12.6%), p=0.007 for interaction term), and in smoking cessation interventions (12.4% vs. 7.7%, difference: 4.7% (95% CI: -0.3%, 9.6%), p=0.02 for interaction term). Intervention clinics performed better on all measures for Medicaid and uninsured pts except cholesterol control, but no differences were statistically significant.

Intervention clinics suggests that, for every 13 pts seeing incentivized clinicians, 1 more pt would achieve BP control. The 7.8% absolute change in BP control for pts with DM represents a 46% relative increase in BP control among intervention pts compared with the baseline of 16.8%. Further research is needed to determine whether this effect of the P4P intervention on BP control increases or decreases over time. However, this NNT to achieve BP control through incentives, taken together with the large relative increase in percentage of pts with BP control and the potential effect of BP control on risk of ischemic vascular events, suggests a reasonable opportunity to reduce morbidity and mortality through P4P as structured in this study.

Limitations: Some clinics exited the program after randomization, with more control clinics leaving than intervention clinics. Additionally, this intervention occurred in the setting of a voluntary QI program. This may reflect a high level of intrinsic motivation to improve among practices in the study, as demonstrated by engagement with the QI specialists.Banerjee D, et al., 2012 (328) 22031453

**Study type:** 3-y, cross-sectional sample using pt EHRs.

- 251,590 pts ≥18 y. Underlying HTN was defined as 2 or more abnormal BP readings ≥140/90 mm Hg and/or pharmaceutical treatment. Appropriate HTN diagnosis was defined by the reporting of ICD-9 codes (401.0–

To identify prevalent and incident HTN cases in a large outpatient healthcare system, examine the diagnosis rates of prevalent and incident HTN, and identify clinical and demographic factors.

- The prevalence of HTN was 28.7%, and the diagnosis rate was 62.9%. The incidence of HTN was 13.3%, with a diagnosis rate of 19.9%. Predictors of diagnosis for prevalent HTN included older age, Asian, African American, higher BMI, and increased number:

- Outpatient EHR diagnosis rates are suboptimal, yet EHR diagnosis of HTN is strongly associated with treatment. Targeted efforts to improve diagnosis should be a priority.
### Jaffe MG, et al., 2013 (329) 23989679

**Aim:** Study the effect of a multipronged, system-based, QI approach on HTN control.

**Study type:** Observational

**Size:** All pts with HTN in the KPNC system were included

<table>
<thead>
<tr>
<th>Inclusion criteria:</th>

</tr>
</thead>
<tbody>
<tr>
<td>350,000 pts in the KPNC system with HTN in 2001, increasing to 650,000 in 2009</td>
<td><strong>Comparator:</strong> Insured pts in California from 2006–2009 who were included in the HEDIS commercial measurement by California health insurance plans participating in the NCQA quality measure reporting process. A 2º comparison group was included to obtain the reported national mean NCQA HEDIS commercial rates of HTN control.</td>
</tr>
</tbody>
</table>

**Eligibility:**
- ≥2 HTN diagnoses coded in primary care visits in the prior 2 y
- ≥1 primary care HTN diagnoses and 1 or more hospitalizations with a 1º or 2º HTN diagnosis in the prior 2 y
- ≥1 primary care HTN diagnoses and 1 or more filled prescriptions for HTN medication within the prior 6 mo, or
- ≥1 primary care HTN diagnoses and 1 or more stroke-related hospitalizations or a history of coronary disease, HF, or DM

**1º endpoint:**
- HTN control rates in KPNC pts with HTN improved from 43.6% (95% CI: 39.4%, 48.6%) in 2001 to 80.4% (95% CI: 75.6%, 84.4%) by the end of the study period (p<0.001 for trend).
- By comparison, national mean NCQA HEDIS commercial measurement HTN control increased from 55.4%–64.1%.
- California mean NCQA HEDIS commercial rates of HTN control were similar to those reported nationally from 2006–2009 (63.4%–69.4%).

**1º Safety endpoint:** N/A

- A system-based approach to HTN control that includes performance measurement and QI strategies led to a significant improvement in HTN control (80%, compared to 44% baseline control) in a large population of pts in a managed care health plan.
Rakotz MK, et al., 2014 (330) 25024244

**Aim:** The goal of this study was to develop a technology-based strategy to identify pts with undiagnosed HTN in 23 primary care practices and integrate this innovation into a continuous QI initiative in a large, integrated health system.

- Of the 139,666 active adult primary care pts in these 23 practices, 47,822 already had a diagnosis of HTN, white-coat HTN, pre-HTN, or elevated BP. The 3 screening algorithms for undiagnosed HTN were applied to the remaining pts' EHRs. There were 1,586 pts who met the criteria of 1 or more of the algorithms and were therefore considered at risk for undiagnosed HTN.

- In phase 1, we reviewed EHRs using algorithms designed to identify pts at risk for undiagnosed HTN. We then invited each at-risk pt to complete an automated office BP protocol. In phase 2, we instituted a QI process that included regular physician feedback and office-based computer alerts to evaluate at-risk pts not screened in phase 1. Study pts were observed for 24 additional mo to determine rates of diagnostic resolution. After phase 1, we established a continuous QI initiative to further evaluate pts who remained at risk for undiagnosed HTN. In this 24-mo follow-up phase (phase 2), all primary care physicians received monthly lists of their pts who continued to be at risk for undiagnosed HTN.

- Of the 1,033 at-risk pts who remained active during phase 2, 740 (72%) were classified by the end of the follow-up period: 361 had HTN diagnosed, 290 had either white coat HTN, pre-HTN, or elevated BP diagnosed, and 89 had normal BP. By the end of the follow-up period, 293 pts (28%) had not been classified and remained at risk for undiagnosed HTN.

- Although we used multiple algorithms to identify pts with elevated BP readings, it is unlikely that we identified all pts with undiagnosed HTN.
These pts were contacted by staff via telephone or letter to arrange a follow-up appointment. These pts remained on the physicians' lists until an automated office BP evaluation was completed or an ICD-9 diagnosis was entered into the chart that indicated the pt's at-risk status had been resolved. In addition, when an at-risk pt arrived for an office visit for any reason, a best practice advisory was prominently displayed on that pt's EHR screen to notify the medical assistant and physician that an automated office BP measurement was needed.

**Aim:** The purpose of this study was to examine the effect of the 2014 expert panel BP management recommendations on pts managed in U.S. ambulatory CV practices.

- Using the National CV Data Registry PINNACLE Registry, we assessed the proportion of 1,185,253 pts who met the 2003 and 2014 panel recommendations, highlighting the populations of pts for whom the BP goals changed.

N/A

- Of 1,185,253 pts in the study cohort, 706,859 (59.6%) achieved the 2003 JNC-7 goals. Using the 2014 recommendations, 880,378 (74.3%) pts were at goal. Among the 173,519 (14.6%) for whom goal achievement changed, 40,323 (23.2%) had a prior stroke or TIA, and 112,174 (64.6%) had CAD. In addition, the average Framingham risk score in pts with HTN, nearly 1 in 7 who did not meet JNC-7 recommendations would now meet the 2014 treatment goals.
this group was $8.5 \pm 3.2\%$, and the 10-y atherosclerotic CVD risk score was $28.0 \pm 19.5\%$.

## Data Supplement 64. RCTs, Meta-analyses, and Systematic Reviews on the Effect of Telehealth Interventions to Improve Hypertension Control (Section 12.3.2)

| Burke LE, et al., 2015 (332) 26271892 | **Aim**: Review of the Scientific Literature on mHealth Tools Related to CVD Prevention  
**Study type**: Systematic review  
**Size**: 69 studies of the use of mobile technologies to reduce CVD risk behaviors  
**Inclusion criteria**: Studies of electronic and mobile technology tools in CV prevention; published from 2004–2014 in English language; enrolling adults except for smoking cessation, for which adolescents were also included; conducted in the U.S. and in developed countries.  
**Exclusion criteria**: Absence of above.  
**Intervention**: Mobile technologies to reduce CVD risk behaviors—varied across studies  
**Comparator**: Varied across studies.  
1° endpoint: Varied across studies.  
1° Safety endpoint: N/A  
Summary: mHealth or mobile technologies have the potential to transform the delivery of health-related messages and ongoing interventions targeting behavior change. Moreover, the use of monitoring devices (e.g., Bluetooth-enabled BP monitors and blood glucose monitors) permits the sharing of important pt self-management parameters with healthcare providers in real time and the delivery of feedback and guidance to pts when they need it. Furthermore, using mHealth tools for monitoring provides the clinician data that far exceed what can be measured in the brief clinical encounter and reflect the status of physiological or behavioral measures in the person's natural setting. |
| Liu S, et al., 2013 (333) 23618507 | **Aim**: Assess the efficacy of e-counselling in reducing BP  
**Inclusion criteria**: 1) Trials that investigated the effect of Internet-based lifestyle interventions on SBP and DBP, 2) trials that included  
**Intervention**: Internet-based intervention as preventive e-counselling or advice using Web sites or e-mails to modify exercise or diet as a  
1° endpoint: MD in BP reduction (Internet-based – usual care); SBP: -3.8 mm Hg (95% CI: -5.63– -2.06), $I^2$=61  
• Behavior change techniques that were used in more than 50% of the successful internet-based interventions included the following: providing information on consequences of behavior in general |
**Study type:** Systematic review, meta-analysis  
**Size:** 13 RCTs or case-control studies

Supplemental components such as mobile text messages, telephone, or in-person support, 3) intervention duration of at least 8 wk, and 4) SBP and DBP reported as 1° or 2° outcome, measured at a clinic or office.

**Exclusion criteria:** Absence of above.

Means of improving BP control. These Internet-based interventions were primarily self-guided, and access was gained via desktop computer, laptop, tablet, or smartphone. The duration of each intervention had to be at least 8 wk in order to achieve clinically meaningful outcomes, including the pt's ability to learn and adhere to complex new behaviors, and to allow for sufficient time to demonstrate a stable reduction in BP. The majority (9/13) of interventions had supplemental components that were not internet-based, such as text messages, in-person visits, and live support and 10/13 targeted both exercise and diet behaviors.

**Comparator:** Usual care with no internet-based strategy.

**DBP:** -2.1 mm Hg (95% CI: -3.51– -0.65), I²=57

**Influence of intervention attributes:**
- **Intervention duration:**
  - Long-term (≥6 mo) intervention: SBP -5.8 mm Hg (95% CI: -4.3– -4.1)  
  - Short-term (<6 mo) intervention: SBP -3.47 mm Hg (95% CI: -5.2– -1.7)
- **DBP mean reduction:** results not reported, not statistically significant.
- **# of behavior change techniques:**
  - ≥5 behavior change techniques: SBP -5.92 mm Hg (95% CI: -7.43– -4.42) / DBP -2.45 mm Hg (95% CI: -3.50– -1.41)  
  - <5 behavior change techniques: SBP -2.69 mm Hg (95% CI: -4.61– -0.78) / DBP -0.02 mm Hg (95% CI: -1.20–1.17)

**1° Safety endpoint:** N/A

**Limitations:**
- HBPT intervention features (telemonitoring systems and self-monitoring programs) as well as inclusion criteria and demographic and clinical characteristics of the comparative groups varied across

---

**Aim:** Review data from RCTs on the effectiveness of HBPT vs. usual care with respect to improvement of BP control, healthcare resources utilization and costs,

**Inclusion criteria:**
- English language  
- Published up to Feb. 2012  
- RCT testing HBPT vs. usual care.

**Intervention:** HBPT had to be based on the use of an electronic automated BP monitor storing values obtained at the pt's home and transferring them to a remote computer

**1° endpoint:** Compared to usual care, HBPT improved:
- Office SBP by 4.71 mm Hg (95% CI: 6.18–3.24; p<0.001; I²=52.2%; p=0.003  
- Office DBP by 2.45 mm Hg (95% CI: 3.33–1.57; p<0.001; I²=40.4%; p=0.048

**Limitations:**
- HBPT intervention features (telemonitoring systems and self-monitoring programs) as well as inclusion criteria and demographic and clinical characteristics of the comparative groups varied across

---

Omboni S, et al., 2013 (334)  
23299557

© 2017 American College of Cardiology Foundation and American Heart Association, Inc.
pt's quality of life and adverse events.

**Study type:** Meta-analysis

**Size:** 23 unique RCTs with 7037 pts (though not all studies reported on all outcomes of interest)

**Exclusion criteria:** Absence of above through a telephone line (wired or wireless), a modem or an Internet connection. At least 1 self BP measurement had to be available for each pt in the intervention group.

**Comparator:** Usual care

- **Office BP Control (<140/90 mm Hg nondiabetic pts and <130/80 mm Hg diabetic pts):** RR: 1.16 (95% CI: 1.04–1.29; p<0.001); I²=69%; p<0.001

**2° endpoint:** Compared to usual care, HBPT improved:

- Greater prescription of antihypertensive medications: weighted MD 0.40 (95% CI: 0.17–0.62; p<0.001); I²=84.2%; p<0.001
- Lower number of office visits: weighted MD -0.18 (95% CI: -0.37–0.00); I²=32.7%; p=0.146
- Quality of life physical component of SF-12 or SF-36 questionnaire: weighted MD 2.78 (95% CI: 1.15–4.41); I²=0.0%; p=0.853
- There was no difference between HBPT and usual care in:
  - Therapeutic adherence [92% HBPT vs. 90% usual care; between-group difference +1.30% (95% CI: -2.31–4.90; p=0.481), I²=0.00%; p=0.888]
  - Quality of life mental component of SF-12 or SF-36 questionnaire: weighted MD -0.11 (95% CI: -1.65–1.43); I²=0.0%; p=0.984

**Cost:** Healthcare costs were significantly higher in the studies and contributed to the high heterogeneity of the studies

- Most studies were powered to test differences in BP lowering, not 2° outcomes

**Summary:** HBPT yielded greater SBP and DBP reductions and a larger proportion of pts achieving BP control than usual care. HBPT vs. usual care resulted in greater prescription of antihypertensive medications and fewer office visits but no difference in therapeutic adherence. Healthcare costs were higher with HBPT than usual care, but when HBPT-related costs were excluded, medical costs were similar between groups. Use of HBPT vs. usual care improved quality of life physical component but not mental. Authors note that the amount of office BP reduction attributable to HBPT was in line with that observed in RCTs of antihypertensive drugs compared with placebo. The estimate was also larger than that usually related to HBP self-monitoring, which speaks in favor of a possible added value of the teletransmission approach.
| Verberk W, et al., 2011 (335) 21527847 | **Aim:** Examine the usefulness of telecare for HTN management | **Inclusion criteria:** 1) Published in the English language, 2) pts were diagnosed as hypertensive and performed BP self-measurement at home, 3) RCTs that compared telecare of BP with usual care, 4) data were transmitted to healthcare providers by telephone, modem, Internet, or mail, and 5) either change in BP or the number of pts that reached their target BP was an outcome and was provided in the study. Date restrictions not reported.  
**Exclusion criteria:** Absence of above | **Intervention:** Telecare for HTN management (treatment and/or coaching). Telecare involved a data transmission process to collect data on a pt's health status to allow remote HTN management. Procedures varied in length and frequency of contact and method of delivery (i.e., often telephone or cell phone with or without internet/computer; with or without behavioral counseling by nurse or pharmacist), often as an adjunct to "usual care" clinical visits. | HBPT group vs. usual care: weighted MD 662.92 (95% CI: 540.81–785.04) euros per pt; I²=99.6%; p<0.001, but costs were similar when only medical costs (excluding HBPT-related costs) were considered (-12.4; 95% CI: -930.52–906.23) euros; p=0.767.  
**Safety endpoint:** No difference was observed in the risk of adverse events (RR: 1.22; 95% CI: 0.86–1.71; p=0.111) | **Limitations:** Telecare intervention methods varied greatly across studies  
**Summary:** Telecare led to a greater decrease in SBP and DBP compared with usual care. Telecare seems a valuable tool to support HTN management. |
Agarwal R, et al., 2011 (27) 21115879

**Aim:** Quantify both the magnitude and mechanisms of benefit (including effect on therapeutic inertia) of home BP monitoring on BP reduction. Therapeutic inertia was defined as no change in medications combined with uncontrolled BP.

**Study type:** Systematic review and meta-analysis

**Size:** 37 RCTs with 9,446 pts. Trial settings included community (n=5), dialysis unit (n=2), general practices (n=18), hospitals and general practice (n=1), and hospital-based outpatient units (n=11).

**Inclusion criteria:** Studies that randomized pts to control or home BP monitoring group

**Exclusion criteria:** Absence of above

**Intervention:** Home BP monitoring as an adjunct to usual care for HTN

**Comparator:** Usual care with BP monitoring in clinic

**1° endpoint:** Compared with usual care alone, home-based BP monitoring:
- Reduced SBP: -2.63 mm Hg (95% CI: -4.24 – -1.02) and
- Reduced DBP: -1.68 mm Hg (95% CI: -2.58– -0.79)
- Greater reduction in SBP by HBPM interventions was seen with added telemonitoring (effect size -3.20; 95% CI: -4.66– -1.73) vs. home BP monitoring (effect size -1.26; 95% CI: -2.20– -0.31; p=0.029). This finding is relevant to telemonitoring

**2° endpoints:**
- More frequent reductions in antihypertensive medication (presumably due to identification of white coat HTN): RR: 2.02 (95% CI: 1.32–3.11)
- Lowered therapeutic inertia (i.e., unchanged medication despite elevated BP: RR for unchanged medication 0.82 (95% CI: 0.68–0.99)

**Limitations:** Different inclusion and exclusion criteria, different BP measurement techniques, drug titration protocols, pt populations, and duration of follow-up across studies likely introduced significant heterogeneity in effect size.

**Summary:** Home BP monitoring leads to a small but significant reduction in SBP and DBP. Greater reduction in SBP is seen when HBPM is accompanied by specific programs to titrate antihypertensive drugs. 1 such strategy is telemonitoring, in which BP readings obtained at home are relayed to the provider who can then take appropriate action, thus reducing therapeutic inertia.

### Study Acronym; Author; Year Published

**Lusignan Sd, et al., 2013 (337) 23536132**

**Aim:** Study the effect of an audit-based education intervention to guidelines/prompts, vs. usual care, to help improve BP control in pts with CKD

**Study type:** Cluster RCT

**Size:** 93 general practices (30 audit-based education intervention, 32 Guidelines/prompts, and 31 usual care)

**Inclusion criteria:** All pts with CKD in the participating practices

**Intervention:** Audit-based education vs. guidelines/prompts

**Comparator:** Usual care

**1st endpoint:** SBP was significantly lower in the audit-based education group (-2.41 mm Hg; 95% CI: 0.59–4.29). There was no significant change in BP in the other 2 groups.

**1st Safety endpoint:** No reports of harm.

- This trial suggests that an intervention that includes specific performance and feedback reports improves BP control in pts with CKD, compared to usual care. To the contrary, the use of practice guidelines and prompts did not improve BP control compared to usual care.

greatest effects or whether certain combinations of individual QI strategies were more “potent” than others.

Summary: QI strategies are associated with improved HTN control. QI strategies improved SBP and the proportion of pts achieving SBP control and had a more modest effect on DBP and the proportion of pts achieving DBP control. Team change (i.e., a focus on HTN by someone in addition to the pt’s physician) had the largest effect on both SBP and DBP. All of the strategies assessed may be beneficial in terms of clinically meaningful reductions in BP under some circumstances and in varying combinations.
| Carter BL, et al., 2009 (321) 19858431 | **Aim:** Determine potency of interventions for BP involving nurses and pharmacists  
**Study type:** Meta-analysis  
**Size:** 37 RCTs of team-based HTN care involving nurse or | **Inclusion criteria:** RCT of team-based HTN care involving nurse or pharmacist intervention  
**Exclusion criteria:** Absence of above | **Intervention:** Team-based HTN care involving nurse or pharmacist intervention  
In nearly all studies involving nurses or pharmacists in clinics, consistent and dedicated case management activities were provided that were distinct from traditional nursing or | SBP/DBP, median reduction: 3.3 mm Hg (IQR: 2.6–10.1)/ 2.8 mm Hg (IQR: 0.4–6.7)  
SBP/DBP control: 13%/ 9% (IQR: 5.3–11.4)  
• Pt reminders  
SBP/DBP, median reduction: 3.3 mm Hg (IQR: 2.3–4.5)/ 0.4 mm Hg (IQR: -2.4–5.0)  
DBP control: 2% (IQR: 1.1–9.4)  
• Team change  
SBP/DBP, median reduction: 9.7 mm Hg (IQR: 4.2–14.0) (p<0.05)/ 4.2 mm Hg (IQR: 0.2–6.8) (p<0.05)  
SBP/DBP control: 22% (IQR: 9.0–33.8)/ 17% (IQR: 5.7–24.5)  
• Financial incentives  
SBP/DBP, median reduction: -13.3 mm Hg/ 0.0 mm Hg (IQR: -2.0–2.5)  
DBP control: 4% (IQR: -1.1–9.4)  
**Safety endpoint:** N/A | **1st endpoint:**  
• OR (95% CI) for controlled BP were: nurses: 1.69 (1.48, 1.93); pharmacists within primary care clinics: 2.17 (1.75, 2.68); and community pharmacists: 2.89 (1.83, 4.55).  
• Mean (SD) reductions in SBP were: nurse intervention: 5.84 (8.05) mm Hg; pharmacists in clinics: 7.76(7.81) mm Hg; and  
• Stepwise regression was used to compare studies that included a given intervention strategy with studies that did not. Several individual components of the interventions were associated with significant reductions in mean SBP including pharmacist recommended medication to physician (-27.21 mm Hg; p=0.002), counseling about lifestyle modification (-12.63 mm Hg; p=0.03), pharmacist performed the intervention (-11.70 mm Hg; p=0.03), use of a treatment |
| Agarwal R, et al., 2011 (27) | **Aim:** Quantify both the magnitude and mechanisms of benefit (including effect on therapeutic inertia) of home BP monitoring on BP reduction. Therapeutic inertia was defined as no change in medications combined with uncontrolled BP.  
**Study type:** Systematic Review and Meta-analysis | **Inclusion criteria:** Studies that randomized pts to control or home BP monitoring group  
**Exclusion criteria:** Absence of above | **Intervention:** Home BP monitoring as an adjunct to usual care for HTN  
**Comparator:** Usual care with BP monitoring in clinic | **1° endpoint:** Compared with usual care alone, home-based BP monitoring:  
- Reduced SBP: -2.63 mm Hg (95% CI: -4.24--1.02) and  
- Reduced DBP: -1.68 mm Hg (95% CI: -2.58--0.79)  
**2° endpoints:**  
- More frequent reductions in antihypertensive medication (presumably due to identification of white coat HTN): RR: 2.02; 95% CI: 1.32--3.11  
- Lowered therapeutic inertia (i.e., unchanged medication despite elevated BP: RR for unchanged medication 0.82 (95% CI: 0.68--0.99)  
**Limitations:** Different inclusion and exclusion criteria, different BP measurement techniques, drug titration protocols, pt populations, and duration of follow-up across studies likely introduced significant heterogeneity in effect size. | Community pharmacists: 9.31 (5.00) mm Hg.  
- There were no significant differences between nurse and pharmacist effects (p≥0.19).  
**Comparator:** Usual care  
**Safety endpoint:** N/A  
**Algorithm:** (-8.46 mm Hg; p<0.001), completion of a drug profile and/or medication history (-8.28 mm Hg; p=0.001), and the overall intervention potency score assigned by the study reviewers (p<0.001). The factors associated with a reduction in DBP were: referral was made to a specialist (~19.61 mm Hg; p=0.04), providing pt education about BP medications (~17.60 mm Hg; p=0.003), completion of a drug profile and/or medication history (~7.27 mm Hg; p=0.006), pharmacist performed the intervention (~4.03 mm Hg; p=0.04), or nurse performed the intervention (~3.94 mm Hg; p=0.04).  
**Summary:** Interventions involving pharmacists or nurses were associated with significantly improved BP control.

prior systematic review)

**Study type:** Systematic review

**Size:** 52 studies of team-based primary care for pts with 1° HTN

**Exclusion criteria:** Inclusion of populations with 2° HTN (e.g., pregnancy) or with a history of CVD (e.g., MI)

collaborated with pts and PCPs were predominantly nurses (28 studies); pharmacists (15 studies); both nurses and pharmacists (5 studies); or community health workers, integrated care managers, or behavioral interventionists (4 studies). Key roles included HTN medication management, active pt follow-up, and adherence and self-management support. Interventions were usually implemented across multiple settings in the healthcare system and in the community, where they were implemented in pharmacies and through home outreach visits.

**Comparator:** Usual care estimate was 12 pct pts (IQI=3.2–20.8 pct pts). Most individual effect estimates in the favorable direction were significant (p<0.05).

• **Reduction in SBP:** The median reduction in SBP was 5.4 mm Hg (IQI=2.0–7.2 mm Hg); Most individual effect estimates were significant (p<0.05).
• **Reduction in DBP:** The overall median reduction in DBP was 1.8 mm Hg (IQI=0.7–3.2 mm Hg) from 38 studies.

**Safety endpoint:** No harm to pts was identified from team-based care interventions in the included studies or the broader literature.

**Stratified analyses for BP outcomes:**
- **Team member role in medication management:** Larger improvements in BP outcomes than overall estimates were demonstrated when team members could make changes to medications independent of the PCP or team members could provide medication recommendations and make changes with the PCP’s approval as compared to team members providing only adherence support and information on medication and HTN.
- **Number of team members added:** Adding ≥2 members demonstrated larger improvements in the proportion of pts with controlled BP and reduction in DBP compared to adding only 1; median reductions in SBP were similar regardless of team size.
- **Improvement in the proportion of pts with controlled BP:** Improved in the proportion of pts with controlled BP was similar for studies from both healthcare and community settings.

**Limitations:** Included studies reported significant differences in pt demographics between intervention and comparison groups at baseline, possible contamination within intervention and comparison groups, and issues related to inadequate description of populations and implemented interventions.

**Summary:** There is strong evidence that team-based care is effective in

| Thomas KL, et al., 2014 (340) 25351480 | **Study type:** Community-based HTN QI program [multifaceted BP control program using a web-based health portal (Heart360), community health coaches, and PA guidance] to improve HTN control in a diverse community setting  
**Design:** Pre-post study without a concurrent control  
**Size:** 1756 pts with HTN from 8 clinics:  
- Median age, 60 y  
- Female, 65.6%  
- African American, 76.1%  
**Inclusion criteria:** Individuals from pt sites >18 y with a previous billing diagnosis of HTN (ICD-9 code 401.X) or a previous clinical diagnosis of HTN in the medical record  
**Exclusion criteria:** Did not reside in Durham County or had a neurocognitive disorder that prevented enrollment | 1st endpoint: 1) Difference in SBP and DBP from enrollment (BP obtained in the clinic at enrollment) to the last BP as measured in clinic within 6 mo after enrollment, 2) proportion of pts that achieved BP <140/90 mm Hg by last clinic visit within 6 mo, and 3) proportion of pts with BP <140/90 mm Hg or drop in SBP ≥10 mm Hg by last visit relative to their enrollment BP.  
Results:  
- Mean change in BP: -4.7 mm Hg (SD ± 21.4) / -2.8 mm Hg (SD ± 11.8) after 6 mo  
- BP control (<140/90 mm Hg) rate: Increased from 51% at baseline to 63% at 6 mo  
- Proportion with BP <140/90 or ≥10 mm Hg decrease in SBP at 6 mo was 69%  
- Among those who were in tiers 1 (BP=140/60–159/99 mm Hg) and 2 (BP≥159/99 mm Hg) at enrollment (n=889), BP change was -8.8 mm Hg (SD ± 15.8) / -5.0 mm Hg (SD ± 10.0) and -23.7 mm Hg (SD ± 26.5) / -10.1 mm Hg (SD ± 14.1), respectively.  
**Summary:** A multicomponent-tiered HTN program that included team-based care with PAs and community health coaches was associated with improved BP control in a diverse community-based population. Though the web-based approach presented technical challenges for some pts, there was a direct association between higher use of Heart360 and larger recorded BP declines as entered into Heart360. This provides some indirect evidence that those pts who were more engaged with their BP self-monitoring achieved better BP control. | **Summary:** |  

| Jaffe MG, et al., 2013 (329) 23989679 | **Study type:** Quasi-experimental evaluation of multi-faceted QI program that included 1) Health system-wide HTN registry, 2) HTN control rates (with provider audit and feedback), 3) | **Inclusion criteria:** Pts identified with HTN within an integrated health care delivery system (KPNC) from 2001–2009  
**1st endpoint:** BP control using NCQA HEDIS measures  
**Results:** BP control increased from 44%–80% from 2001–2009 with the KPNC QI program compared to 55.4% to 64.1% for the national mean and 63.4% to | **Summary:** Implementation of a large-scale HTN program was associated with a significant increase in HTN control compared with state and national control rates. |
Evidence-based practice HTN guideline, 4) medical assistant visits for follow-up measurements with no pt copayment for these follow-up visits, and 5) promotion of single-pill combination therapy.

**Design:** Contemporaneous control group external to healthcare system

**Size:** Kaiser HTN registry increased from 349,937 pts in 2001 to 652,763 in 2009.

**Exclusion criteria:** None stated

69.4% for the Ca mean from 2006 to 2009 NCQA HEDIS commercial measurement comparison groups.

<tr>
<td><strong>Aim:</strong> The aim of this study was to evaluate the effectiveness of renal indicators outlined in P4P on the management of HTN in primary care. To estimate the cost implications of the resulting changes in prescribing patterns of antihypertensive medication following introduction of such indicators.</td>
</tr>
<tr>
<td><strong>Study type:</strong> Prospective cohort study using a large primary care database.</td>
</tr>
<tr>
<td><strong>Inclusion criteria:</strong> A total of 10,040 pts had confirmed stage 3–5 CKD in the 2 y pre-QOF and formed the study cohort.</td>
</tr>
<tr>
<td><strong>Exclusion criteria:</strong> None</td>
</tr>
<tr>
<td><strong>Intervention:</strong> The implementation of national estimated GFR reporting and the inclusion of renal-specific indicators in a primary care P4P system since April 2006 has promoted identification and better management of risk factors related to CKD. In the UK, the P4P framework is known as the QOF.</td>
</tr>
<tr>
<td><strong>Comparator:</strong> N/A</td>
</tr>
<tr>
<td>**Mean age of the cohort at the start of the study period was 64.8 y, 55% were female. In those pts with stage 3–5 CKD 83.9% were hypertensive, defined by a pre-P4P BP of &gt;140/85 or currently taking antihypertensive medication. The proportion of pts with CKD 3–5 attaining the BP target of 145/80 increased from 41.5% in the pre-QOF period to 50.0% in the post-QOF period. This increase was even more marked for those with HTN in the pre-QOF period (28.8%–45.1%). In the hypertensive pts, mean BP fell from 146/79 mm Hg to 140/76 in the first 2 y post-P4P [p&lt;0.01, analysis of variance].</td>
</tr>
<tr>
<td><strong>Summary:</strong> Population BP control has improved since the introduction of P4P renal indicators, and this improvement has been sustained. This was associated with a significant increase in the use of antihypertensive medication, resulting in increased prescription cost. Longer-term follow-up will establish whether or not this translates to improved outcomes in terms of progression of CKD, CVD and pt mortality.</td>
</tr>
<tr>
<td><strong>Safety endpoint:</strong> N/A</td>
</tr>
</tbody>
</table>

| for both levels and the 4th paid no incentives. (19–20 physicians in each group) |
| appropiate response measure was 8.84% (95% CI: 4.20%–11.80%) for the individual group, 3.70% (95% CI: 0.24%, 7.68%) for the practice group, 5.54% (95% CI: 1.92%–9.52%) for the combined group, and 0.47% (95% CI: −3.12%–4.04%) for the control group. The adjusted estimated absolute difference over the study in the change between the proportion of the physician’s pts achieving BP control or receiving an appropriate response for the individual incentive group and the controls was 8.36% (95% CI: 2.40%–13.00%; p=0.005). |

Financial incentives may constitute an insufficiently strong intervention to influence goal commitment when providers attribute performance to external forces beyond their control.
This cohort was taken from a database collated as part of a clinical decision support system used to assist the management of CKD in primary care.

**Size:** 90,250 pts on general practitioner registers with a valid serum creatinine estimation in the 6-y study period. A total of 10 040 pts had confirmed stage 3–5 CKD in the 2 y pre-QOF and formed the study cohort.

BP reduction was sustained in the last 2 y of the study, 139/75 (p<0.01, analysis of variance). The proportion of hypertensive pts taking ACEIs or angiotensin blockers increased, this was also sustained in the third time period. An increase in the prescribing of diuretics, CCBs and BBs was also observed. The additional cost of increased prescribing was calculated to be euro 25.00 per hypertensive pt based on GP prescription data.

| **Aim:** The aim of this study was to evaluate the effectiveness of renal indicators outlined in P4P on the management of HTN in primary care. To estimate the cost implications of the resulting changes in prescribing patterns of antihypertensive medication following introduction of such indicators. | **Inclusion criteria:** Pts with HTN diagnosed between Jan. 2000–Aug. 2007. **Exclusion criteria:** None | **Intervention:** The UK P4P incentive (the Quality and Outcomes Framework), which was implemented in April 2004 and included specific targets for general practitioners to show high quality care for pts with HTN (and other diseases). **Comparator:** None | **After accounting for secular trends, no changes in BP monitoring: level change: 0.85 (95% CI: −3.04–4.74), p=0.669 and trend change: −0.01, (95% CI: −0.24–0.21), p=0.615, control: −1.19 (95% CI: −2.06–1.09), p=0.109 and −0.01 (95% CI: −0.06–0.03), p=0.569, or treatment intensity; 0.67: (95% CI: −1.27–2.81), p=0.412 and 0.02 (95% CI: −0.23–0.19, p=0.706 were attributable to P4P. P4P had no effect on the cumulative incidence of stroke, MI, renal failure, HF, or all-cause mortality in both treatments experienced and newly treated subgroups. **Summary:** Good quality of care for HTN was stable or improving before P4P was introduced. P4P had no discernible effects on processes of care or on HTN related clinical outcomes. Generous financial incentives, as designed in the UK P4P policy, may not be sufficient to improve quality of care and outcomes for HTN and other common chronic conditions. |

Serumaga B, et al., 2011 (344) 21266440
Bardach NS, et al., 2013 (327) 24026600

**Aim:** To assess the effect of P4P incentives on quality in EHR-enabled small practices in the context of an established QI initiative.

**Study Type & Size:** A cluster-randomized trial of small (<10 clinicians) primary care clinics in New York City from April 2009–March 2010.

<table>

<tbody>
<tr>
<td><strong>Participating clinics (n=42 for each group)</strong> had similar baseline characteristics, with a mean of 4,592 (median, 2,500) pts at the intervention group clinics and 3,042 (median, 2,000) at the control group clinics.</td>
<td></td>
</tr>
<tr>
<td>A city program provided all participating clinics with the same EHR software with decision support and pt registry functionalities and QI specialists offering technical assistance.</td>
<td></td>
</tr>
<tr>
<td>Incentivized clinics were paid for each pt whose care met the performance criteria, but they received higher payments for pts with comorbidities, who had Medicaid insurance, or who were uninsured (maximum payments: $200/pt; 100,000/clinic). Quality reports were given quarterly to both the intervention and control groups.</td>
<td></td>
</tr>
<tr>
<td>Intervention clinics had greater adjusted absolute improvement in rates of appropriate antithrombotic prescription (12.0% vs. 6.1%, difference: 6.0% (95% CI: 2.2%–9.7%; p=0.001 for interaction term)), BP control (no comorbidities): 9.7% vs. 4.3%, difference: 5.5% (95% CI: 1.6%–9.3%; p=0.01 for interaction term); with DM: 9.0% vs. 1.2%, difference: 7.8% (95% CI: 3.2%–12.4%; p=0.007 for interaction term); with DM or ischemic vascular disease: 9.5% vs. 1.7%, difference: 7.8% (95% CI: 3.0%–12.4%; p=0.007 for interaction term), and in smoking cessation interventions (12.4% vs. 7.7%, difference: 4.7% (95% CI: -0.3%–9.6%; p=0.02 for interaction term). Intervention clinics performed better on all measures for Medicaid and uninsured pts except cholesterol control, but no differences were statistically significant.</td>
<td></td>
</tr>
</tbody>
</table>

**Summary:** In our study, although the effect of the intervention was lower than the 10% improvement that we estimated a priori, the absolute risk reduction for BP control among pts with DM was 7.8% (NNT, 13). This suggests that, for every 13 pts seeing incentivized clinicians, 1 more pt would achieve BP control. The 7.8% absolute change in BP control for pts with DM represents a 46% relative increase in BP control among intervention pts compared with the baseline of 16.8%. Further research is needed to determine whether this effect of the P4P intervention on BP control increases or decreases over time. However, this NNT to achieve BP control through incentives, taken together with the large relative increase in percentage of pts with BP control and the potential effect of BP control on risk of ischemic vascular events, suggests a reasonable opportunity to reduce morbidity and mortality through P4P as structured in this study.

**Limitations:** Some clinics exited the program after randomization, with more control clinics leaving than intervention clinics. Additionally, this intervention occurred in the setting of a voluntary QI program. This may reflect a high level of intrinsic...
Maimaris W, et al., 2013 (345) 23935461

**Aim:** To assess strategies for influencing HTN care including procurement of essential medications, the existence of simple national guidelines for HTN management, introduction of financial incentives for health care practitioners to diagnose or treat HTN, and enhanced health insurance coverage.

**Study type:** Systematic review examining the effect of national or regional health system arrangements on HTN care and control

**Study selection criteria based on:**
1) HTN awareness. Defined as pts with clinically measured hypertensives who have been diagnosed by a health care professional as hypertensive.
2) HTN treatment. Defined as the use of at least 1 antihypertensive medication in a pt with known HTN.
3) Antihypertensive medication adherence. Defined as consistently taking the antihypertensive medication regimen as prescribed by the health care provider.
4) HTN control: defined as the achievement of BP<140/90 mm Hg (or other explicitly defined threshold) in individuals being treated for HTN, or, alternatively, measured by the mean BP amongst individuals with HTN.

- The screening process is described using an adapted PRISMA flowchart. 5,514 articles were screened by title and abstract for inclusion. The full text of 122 of the 5,514 articles was obtained and assessed for eligibility. 53 studies met eligibility criteria for this review. 51 of the included studies were quantitative and 2 were qualitative. Of the 51 quantitative studies, 1 was an RCT; 12 were cohort studies, 2 of which were retrospective; 3 were case-control studies; 32 were cross-sectional studies; and 3 were ecological studies. 42 of the 53 studies (79%) were carried out in countries classified by the World Bank as high-income countries, 36 of which were in the U.S. 6 studies were carried out in upper middle-income countries, 3 in lower middle-income countries.

- Health insurance status: 15 cross-sectional studies reported comparisons of HTN outcomes in insured and uninsured pts. 8 of these 15 studies reported that insurance was associated with improved HTN treatment, control or medication adherence. The 7 other cross-sectional studies that compared HTN outcomes in insured pts and uninsured pts, reported no significant negative or positive associations between insurance status and HTN outcome.

- Medication costs or medication co-payments: All 6 of these studies reported significant associations between reduced co-payments or costs and improved HTN control or medication adherence.

- Co-payments for medical care: 14 quantitative studies measured the association of medication co-payments or costs with HTN control or treatment adherence, 9 of which were set in the U.S., and 1 in each of Cameroon, China, Finland, Israel, and Brazil. 2 of the 14 studies had a low risk of bias. 7 of the 14 studies were cohort studies, 1 was a case-control study, and 6 were cross-sectional studies. All 7 cohort studies are described in more detail in the systematic review.

- Although lacking longitudinal studies, we found a large positive association between having a routine physician or place of care for HTN management and treatment, awareness, control, and adherence to antihypertensive treatment, again in the U.S. publication and reporting bias noted by authors.
|   |   | countries, and 1 in a low-income country. | studies reported associations between increased medication costs or co-payments and reductions in HTN control or reduced adherence to antihypertensive medication, although for 1 of these 7 cohort studies, the association between increased copayments and reduced medication adherence was only found for low medication co-payments, and at high co-payment levels medication adherence was actually found to increase (OR for medication adherence vs. baseline of 1 for $0 co-payments was 0.72 for $1–$9 co-payments (p=0.05), 1.02 for $10–$29 co-payments (p=0.05), and 1.32 for co-payments . $30 (p=0.05)

- Physician remuneration models: 2 studies evaluated the association of physician remuneration models with HTN control or treatment adherence, 1 an ecological study set in Canada, and 1 a U.S. cross-sectional study. Neither study had a low risk of bias. The U.S. study reported improved rates of HTN control amongst pts treated under a capitation model compared to fee-for-service pts (adjusted OR for HTN control: 1.82 (95% CI: 1.02–3.27) for capitation vs. fee-for-service pts). The Canadian study reported highest rates of HTN control amongst pts treated under a capitation model compared to fee-for-service pts (adjusted OR for HTN control: 1.82 (95% CI: 1.02–3.27) for capitation vs. fee-for-service pts). |   |
| Treatment and control among practices using a capitation model, compared to fee-for-service and salary model. HTN awareness levels were highest in practices with a fixed salary remuneration model. |
Colors correspond to COR in Table 1. For all medical therapies dosing should be optimized and serial assessment exercised.

*See text for important treatment directions.

†Hydral-Nitrates Green Box- The combination of ISDN/HYD with ARNI has not been robustly tested. BP response should be carefully followed.

‡See 2013 HF guideline.

§Participation in investigational studies is also appropriate for stage C, NYHA class II and III HF.

ACEI indicates angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; ARNI, angiotensin receptor-neprilysin inhibitor; BP, blood pressure; bpm, beats per minute; C/I, contraindication; CRT-D, cardiac resynchronization therapy-device; COR, class of recommendation; Dx, diagnosis; GDMT, guideline-directed management and therapy; HFrEF, heart failure with reduced ejection fraction; ICD, implantable cardioverter-defibrillator; ISDN/HYD, isosorbide dinitrate hydral-nitrates; LBBB, left bundle-branch block; LVEF, left ventricular ejection fraction.
ejection fraction; LVAD, left ventricular assist device; NSR, normal sinus rhythm; and NYHA, New York Heart Association.

### Data Supplement E. Examples of Hypertension Quality Improvement Strategies

<table>
<thead>
<tr>
<th>Quality Improvement Strategy</th>
<th>Examples</th>
</tr>
</thead>
</table>
| Audit and feedback on performance | • Feedback of performance to individual providers  
• Benchmarking – provision of outcomes data from top performers for comparison with provider’s own data  
• Performance measures, quality indicators and reports  
• Use of registries to track BP control status at system and provider levels |
| Provider education | • In person, online, or other education to improve BP measurement and management skills  
• Training to improve communication, cultural competency, and ability to inspire and support lifestyle modification |
| Patient education | • Intensive education strategies promoting hypertension self-management  
• Cultural and linguistic tailoring of materials to increase acceptability |
| Promotion of self-management | • Reduce barriers for patients to receive and adhere to medications and to implement lifestyle modification |
| Patient reminder systems (for follow-up appointments, BP checks, and self-management) | • Postcards, calls, texts, or emails to patients  
• Telehealth-delivered reminders |
| System change | • Standardization of BP measurement using an automated device and standardized protocol  
• Screening to identify all patients eligible for hypertension management  
• Systematic follow-up of patients for the initiation and intensification of antihypertensive therapy  
• Decision support to providers to guide protocol-based treatment decisions  
• Physician or other clinical champion designated to lead hypertension care improvement initiatives  
• Hypertension specialist available for consult  
• Partner with community resources to support BP management |

BP indicates blood pressure.
